Contents

29. Exploring the exogenous and endogenous effects of melatonin on spinal cord injury

Dewan Md. Sumsuzzman, Kanghui Park, and Yonggeun Hong

30. High-intensity interval training in individuals with spinal cord injury

Byron Lai, Jereme Wilroy, and Gordon Fisher

31. Stem cells and chronic spinal cord injury: Overview

Leonardino A. Digma, Pavan S. Upadhyayula, Joel R. Martin, and Joseph D. Ciacci

This page intentionally left blank

Contributors

Numbers in parentheses indicate the pages on which the authors' contributions begin.

L. Abou (117), Department of Kinesiology and Community Health, University of Illinois at Urbana-Champaign, Urbana, IL, United States

Monzurul Alam (245), Department of Biomedical Engineering, The Hong Kong Polytechnic University, Hong Kong

George A. Alexiou (191), Department of Neurosurgery, University Hospital of Ioannina, Ioannina, Greece

Preface

Spinal injury affects about 10 million people annually worldwide. Many of these injuries are preventable and occur due to falls, violence, and road traffic accidents. However, spinal cord damage may also result from nontraumatic injury, for example, due to toxins, infection, cancer, intervertebral disc damage, and vascular disease.

Spinal injuries may cause significant, lifelong disabilities and thereby impact the family unit. Symptoms are varied and include paresthesia, spasticity, and loss of motor control. In extreme cases, affected individuals are chair- or bedbound for life. These debilitating injuries may also be accompanied by severe pain. Loss of bladder and bowel control increases dependency and further reduces quality of life.

Diagnosis is generally based on symptoms and various imaging techniques in the clinical context of a traumatic injury to the spinal cord. Various syndromes are associated with spinal cord injury (e.g., central, anterior, and posterior cord syndromes). However, a variety of pathological processes are involved in the initiation of primary and secondary damage to the spinal cord.

Physical trauma may be accompanied by multiorgan cellular and biochemical injury. These injuries include neurodegeneration, free radical damage, changes in gene expression, and physiological changes such as loss of the regulation of blood pressure. So the manifestation of symptoms and signs from any given injury may be highly variable.

The patient's functional outcome predominantly depends on the level of spinal column injury (i.e., cervical, thoracic, lumbar, or sacral), the location of the damage within the spinal cord (e.g., central, anterior, posterior), and the severity. This functional outcome may be modified to some extent by medical therapies and rehabilitation.

To fully comprehend and positively influence the trajectory of patients' outcomes, it is necessary to understand the fundamental principles of the conditions that arise as a result of spinal cord injury. Presently, the availability of much of this information is sporadic, in different scientific domains, and designed for different scientific specialties. Spinal cord injuries are diverse, so a multidisciplinary approach is needed. This is addressed in the two-volume set *The Neuroscience of Spinal Cord Injury* comprising the 2 books:

Diagnosis and Treatment of Spinal Cord Injury
Cellular, Molecular, Physiological, and Behavioral Aspects of Spinal Cord Injury

This book, *Diagnosis and Treatment of Spinal Cord Injury*, has the following six sections:

- *Setting the scene: introductory chapters*
- *Clinical features of spinal injury*
- *Diagnosis and evaluation*
- *Treatments: experimental and clinical*
- *Rehabilitation in spinal injury*
- *Resources*

Each chapter has the following sections:

- *An abstract (published online)*
- *Key facts*
- *Mini-dictionary of terms*
- *Applications to other areas of neuroscience*
- *Summary points*

The sections *Key facts, Mini-dictionary of terms,* and *Summary points* enable the reader to cross the transintellectual and transdisciplinary divides. The section *Applications to other areas of neuroscience* presents the translational aspects of the chapter and the applicability of the information.

The Neuroscience of Spinal Cord Injury is designed for research and teaching purposes. It is suitable for neurologists, surgeons, trauma specialists, psychologists, health scientists, public health workers, doctors, pharmacologists, and research scientists. It is valuable as a personal reference book and also for academic libraries that cover the domains of trauma and neurology. Contributions are leading national and international experts including those from world-renowned institutions. It is suitable for undergraduate and postgraduate students as well as lecturers and academic professors.

Chapter 1

Traumatic spinal cord injury and outcomes in low-resource settings

Avital Yohann, Laura N. Purcell, and Anthony Charles
Department of Surgery, University of North Carolina, Chapel Hill, NC, United States

Abbreviations

ASIA	American Spinal Injury Association
ATLS	advanced trauma life support
CT	computerized tomography
GSW	gunshot wound
HIC	high-income country
ICU	intensive care unit
LMIC	low- and middle-income country
MRI	magnetic resonance imaging
RTI	road traffic injury
TSCI	traumatic spinal cord injury
YLD	years lived with disability

Introduction

Traumatic spinal cord injuries (TSCIs) are devastating under any circumstance. However, patients in low-resource settings face unique challenges as they experience delays to care, a lack of prehospital care, and limited proper immobilization during transport, resulting in significantly higher in-hospital mortality than patients in high-income countries (HICs) (Bickenback, 2013; Eaton, Mukuzunga, Grudziak, & Charles, 2019; Lakhey, Jha, Shrestha, & Niraula, 2005). While long-term mortality of TSCI in HICs is now primarily due to chronic diseases, TSCI patients in low-income countries continue to die of preventable secondary causes (Bickenback, 2013). Those who survive struggle with access to proper assistive devices, rehabilitation services, follow up and health maintenance, and community reintegration (Bickenback, 2013). Moreover, while TSCI incidence is stable or decreasing in HICs, rates in low- and middle-income countries (LMICs) continue to rise (Jazayeri, Beygi, Shokraneh, Hagen, & Rahimi-Movaghar, 2015). Though most of the available evidence regarding the epidemiology and outcomes of TSCIs comes from HICs, the limited data from LMICs provide essential insights into improving TSCI prevention and management. This chapter will discuss the epidemiology, etiology, treatments, and outcomes of TSCIs in different LMICs globally.

Epidemiology

The worldwide incidence of traumatic spinal cord injury (TSCI) is between a quarter and 1 million people annually (Bickenback, 2013). The Global Burden of Disease Study reported a global age-standardized incidence rate of 13 per 100,000 and a prevalence of 368 per 100,000 in 2016. The regions with the highest reported incidence of TSCIs are central and eastern Europe and central Asia. Because of armed conflict, Syria, Yemen, Iraq, and Afghanistan have the highest incidence (James et al., 2019) (Fig. 1). The incidence of TSCI appears to be stable or decreasing in HICs, but increasing in LMICs (Jazayeri et al., 2015). In 2016, TSCIs were responsible for an estimated 9.5 million years lived with disability (YLDs) (James et al., 2019). Available evidence on the epidemiology of TSCIs comes from HICs, but the limited data from LMICs provide essential insight into improving TSCI prevention and management strategies.

Diagnosis and Treatment of Spinal Cord Injury. https://doi.org/10.1016/B978-0-12-822498-4.00001-4

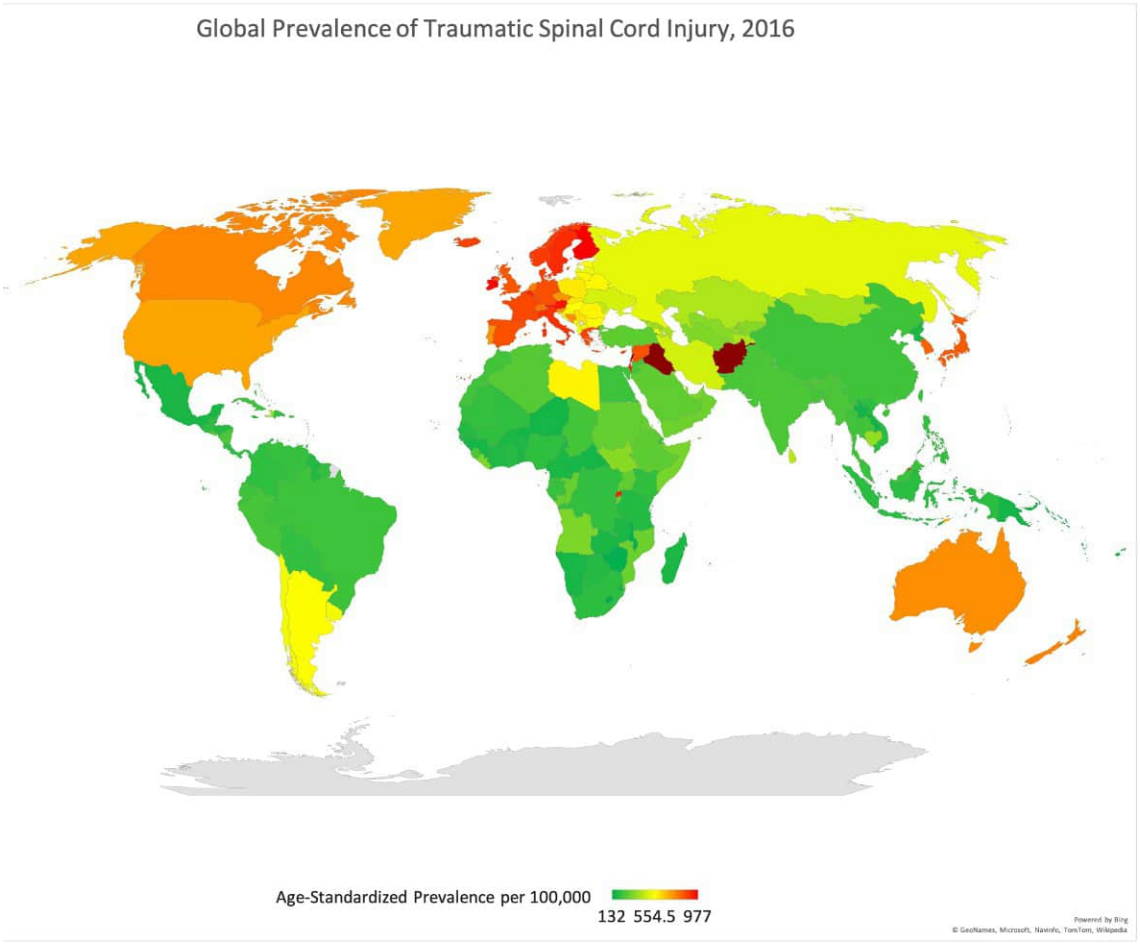

FIG. 1 Global prevalence of traumatic spinal cord injury. The figure illustrates the age-standardized prevalence of TSCI per 100,000 people by country in 2016 (James et al., 2019). The countries with prevalence over 1300 per 100,000, shown in *dark red*, are Lebanon, Iraq, and Afghanistan.

Sex and age

Males are disproportionately affected by TSCIs (Kang et al., 2017), with some countries reporting a male preponderance of over 90% (Deconinck, 2003; Gosselin & Coppotelli, 2005). Males are more likely to be in situations that place them at risk for TSCI or participate in high-risk activities (Kang et al., 2017) (Fig. 2).

In HICs, TSCIs follow a bimodal age distribution, with one peak in the second to third decade and another peak after age 65 (Kang et al., 2017). In LMICs, TSCIs predominantly affect younger patients. In the Eastern Mediterranean (specifically Iran, Pakistan, and Afghanistan), the mean age range is 26–38 years (Chabok et al., 2010; Deconinck, 2003). Similarly, in Southeast Asia, Sub-Saharan Africa, and Latin America, the mean age is 30–44 years (Barbetta et al., 2018; Bellet, Rashid, Jusabani, Dekker, & Temu, 2019). Studies in China and India report a mean age range of 45–51 years (Aleem et al., 2017; Zhou et al., 2016).

Etiology

The most common cause of TSCIs in most regions is falls, followed by road traffic injuries (RTIs) (James et al., 2019).

Falls

Falls are the most common cause of TSCIs in Southeast Asia, parts of the Eastern Mediterranean, Sub-Saharan Africa, and the Western Pacific. In Southeast Asia, falls are responsible for 53%–84% of TSCIs (Bellet et al., 2019; Dhakal, Paudel, Dhungana, Gurung, & Kawaguchi, 2018). Falls in these regions are primarily occupation-related (Agarwal, Sud, &

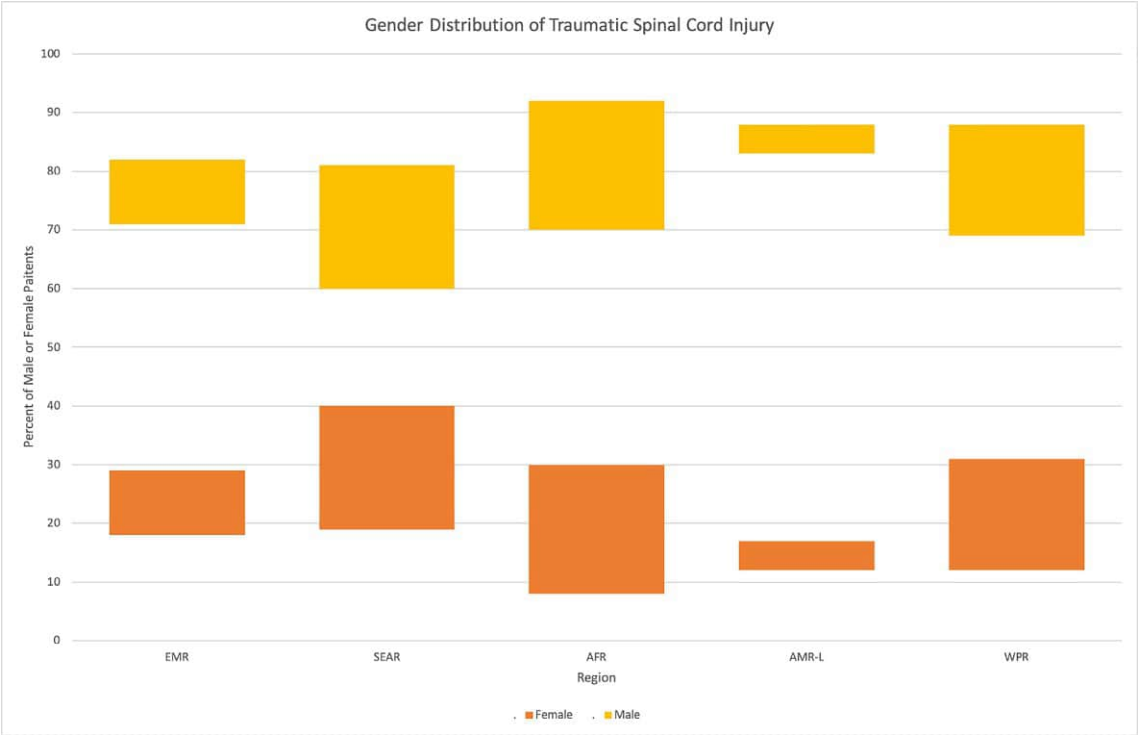

FIG. 2 Gender distribution of traumatic spinal cord injury by region. The range of proportions of spinal cord injured patients by sex is shown by region. *EMR*, Eastern Mediterranean; *SEAR*, Southeast Asia; *AFR*, Africa; *AMR-L*, Latin America; *WPR*, Western Pacific.

Shishehbor, 2016; Dhakal et al., 2018). In Iran and Pakistan, construction workers and well diggers are at high risk for falls due to unsafe work environments (Derakhshanrad, Yekaninejad, Vosoughi, Sadeghi Fazel, & Saberi, 2016; Rathore, Hanif, Farooq, Ahmad, & Mansoor, 2008). In Sub-Saharan Africa, falls are common from roofs, scaffolds, trees, or electric poles (Leidinger et al., 2019; Löfvenmark et al., 2015). In Cambodia, approximately 50% of TSCIs are secondary to falls from trees or houses (Choi et al., 2017; Makhni et al., 2019). Malaysia's high rates of falling TSCIs are attributed to migrant workers in high-risk conditions with limited safety regulations (Ibrahim et al., 2013). In China, falls are responsible for over 60% of TSCIs due to increased construction of buildings and subways (Liu et al., 2012; Liu, Liu, Gao, Li, & Li, 2020).

Falls from standing are also common. LMIC's growing aging population has resulted in more individuals vulnerable to TSCIs from ground-level falls (Yuan, Shi, Cao, Li, & Feng, 2018). Also, ground-level falls while carrying heavy objects atop one's head are common, particularly for females in Sub-Saharan Africa (Moshi, Sundelin, Sahlen, & Sörlin, 2017).

Road traffic injuries

RTIs are the most common cause of TSCIs in Sub-Saharan Africa, Latin America, and parts of the Western Pacific. Studies from Ghana, Nigeria, and Botswana report up to 80% of TSCIs are due to RTIs (Ametefe et al., 2016; Löfvenmark et al., 2015). While in Malawi, Tanzania, and Sierra Leone, RTIs and falls are evenly distributed (Eaton, Hanif, Grudziak, & Charles, 2017; Gosselin & Coppotelli, 2005). In Latin America, 39%–44% of TSCIs are due to RTIs (Bellucci et al., 2015). Within the Western Pacific, RTIs are the most common cause of TSCI in Malaysia, responsible for 66% of cases (Ibrahim et al., 2013). One-third of TSCIs in Cambodia are due to RTIs, most of which can be attributed to motorcycle collisions (Choi et al., 2017; Makhni et al., 2019).

RTIs have surpassed falls as the leading cause of TSCIs in locations with rapid increases in motorization. In Brazil, RTIs are the leading etiology of TSCI in 2003, as the number of motorcycles in Brazil has increased by 491% (Bellucci et al., 2015). In high population centers in China, such as Beijing, RTIs have surpassed falls as the most common cause of TSCIs, as the number of private vehicles has increased from 1.2 million in 2002 to 4.8 million in 2010 (Chen et al., 2017; Hua et al., 2013; Yuan et al., 2018). Factors contributing to high rates of RTIs in Sub-Saharan Africa and other LMICs include lack of road maintenance, unsafe driving, road unworthy vehicles, and poor enforcement of traffic laws (Ametefe et al., 2016; Chen et al., 2017; Obalum, Giwa, Adekoya-Cole, & Enweluzo, 2009).

Violence and other causes

Violence has generally become a less common cause of TSCIs worldwide. However, in areas with active conflict and terrorism, such as in North Africa and the Middle East (specifically Syria, Yemen, Iraq, and Afghanistan), it is the most common cause of TSCIs (James et al., 2019). A study in Afghanistan found 59% of TSCI cases were due to bullets or shrapnel (shelling, gunshots, and mine explosions) (Deconinck, 2003). In Brazil, gun violence is responsible for nearly 30% of TSCIs (Barbetta et al., 2018; Bellucci et al., 2015). In South Africa, violence is a significant contributor, as up to 60% of TSCIs are attributed to gun violence, stabbing, and blunt assault mechanisms (Eaton et al., 2019; Löfvenmark et al., 2015). Assault is a less commonly reported cause of TSCIs in the rest of Sub-Saharan Africa, accounting for 2%–10% (Eaton et al., 2019; Löfvenmark et al., 2015).

Finally, sports-related activities compose a small proportion of TSCIs globally, such as diving into shallow water (6%–12% of Brazil's TSCIs), winter sports ($\leq$5% of TSCIs in China) (Bellucci et al., 2015; Chen et al., 2017; Liu et al., 2020). In Sub-Saharan Africa, specifically Nigeria and Botswana, sports-related activity is responsible for an estimated 2% of TSCIs (Löfvenmark et al., 2015; Obalum et al., 2009). A study from Iran reported a relationship between education level and TSCI etiology. Sports become a more common cause of TSCI with increasing years of education (primarily diving, gymnastics, wrestling), while violence and being struck by falling objects became less common (Derakhshanrad et al., 2016).

Spinal cord level and severity

Overall complete cervical injuries are the most common, however significant TSCI level and severity variations exist globally (Kang et al., 2017). For example, the thoracic spine is the most commonly injured spinal level in Pakistan, Iran, and Afghanistan, with cervical injuries composing 30% of TSCIs (Deconinck, 2003; Derakhshanrad et al., 2016; Rathore et al., 2008). However, most Afghani patients have complete thoracic or lumbar injuries, and only 7% have cervical injuries, which is reflected in improved survival (Deconinck, 2003).

In Sub-Saharan Africa, the cervical spine is the most common injured site (30%–68% of cases), followed by the thoracic (10%–39%) and lumbar spine (4%–59%) (Ametefe et al., 2016; Bellet et al., 2019). Injury severity, however, varies significantly. In South Africa, Malawi, Tanzania, and Ghana, complete injuries range from 23% to 48% of patients, whereas up to 92% of TSCIs are complete in Nigeria and Sierra Leone (Ametefe et al., 2016; Bellet et al., 2019; Gosselin & Coppotelli, 2005; Obalum et al., 2009).

In Brazil, the most common location of TSCI is the thoracic spine (46%–61%), with approximately 60% being complete (Barbetta et al., 2018; Bellucci et al., 2015). Cervical injuries in Brazil were more common in automobile collisions, whereas thoracic injuries were more associated with motorcycle collisions and GSWs (Barbetta et al., 2018).

In China, 47%–76% of TSCIs are reported to be cervical, and 14%–55% of injuries are complete (Chen et al., 2017). Beijing has higher tetraplegia rates and complete injuries than other regions in China (Yuan et al., 2018). The cervical spine is generally the most common location of injury in Southeast Asia and the Western Pacific. In both regions, falls are associated with lumbar injuries and motorcycle and automobile collisions with cervical injuries (Agarwal, Upadhyay, & Raja, 2007; Choi et al., 2017). In Cambodia, lumbar injuries are more common than cervical injuries (Fig. 3) (Choi et al., 2017; Makhni et al., 2019).

Diagnosis

Diagnosis of TSCI relies on a combination of history and clinical findings with the use of radiographic adjuncts. Clinical findings include flaccid paralysis and lack of response to painful stimuli below the level of injury, as well as bradycardia, priapism, and paradoxical breathing (Kebaish & Harris, 2020).

A complete TSCI produces total loss of all motor and sensory function below the level of injury. Nearly 50% of all TSCIs are complete. Even with a complete TSCI, the spinal cord is rarely completely transected. More commonly, loss of function is caused by a contusion to the spinal cord or ischemia of the spinal cord. In an incomplete TSCI, some function remains below the primary level of the injury.

Clinicians commonly utilize the American Spinal Injury Association (ASIA) grading scale to describe the injury severity (Kirshblum et al., 2011).

- ASIA A: a complete spinal cord injury with no sensory or motor function preserved
- ASIA B: an incomplete sensory injury with complete motor function loss

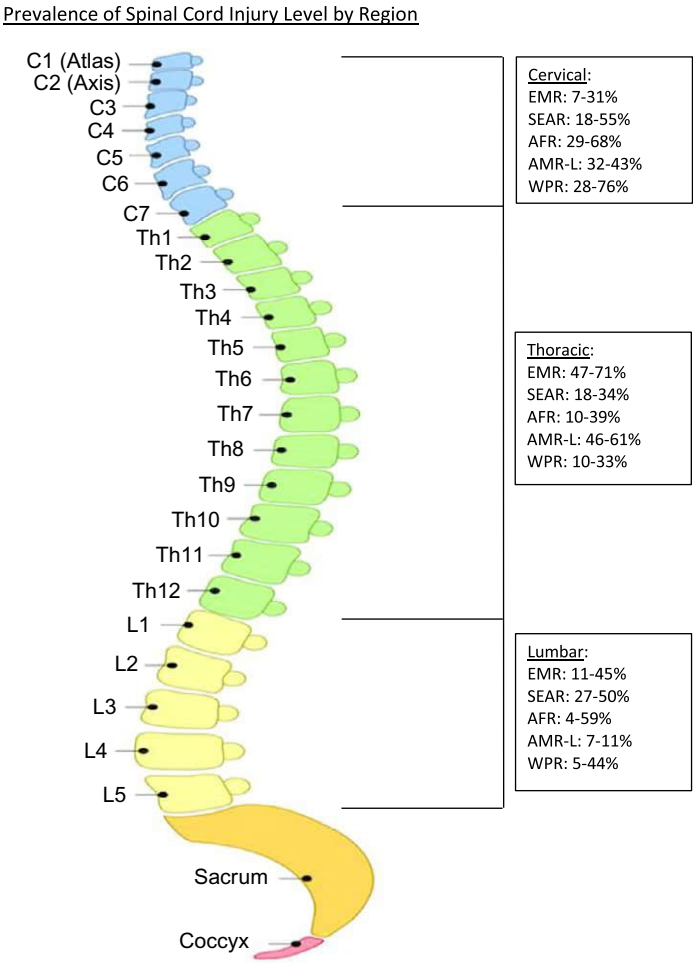

FIG. 3 Distribution of traumatic spinal cord injury level by region. The range of prevalence of injuries at different spinal levels across regions is reported from the available literature. *EMR*, Eastern Mediterranean; *SEAR*, Southeast Asia; *AFR*, Africa; *AMR-L*, Latin America; *WPR*, Western Pacific.

- ASIA C: an incomplete motor injury, where there is some movement, but less than half the muscle groups are anti-gravity (can lift against the force of gravity with a full range of motion)
- ASIA D: an incomplete motor injury with more than half of the muscle groups are anti-gravity
- ASIA E: normal

The more severe the injury, the less likely recovery will occur. Historically, the radiological diagnosis of TSCI started with plain spine radiography. However, with the technological advancements and availability, the entire spine may be imaged with computerized tomography (CT) as an initial screen to identify fractures and other bony abnormalities. For patients with known or suspected injuries, magnetic resonance imaging (MRI) helps delineate spinal cord anatomy and detect any blood clots, herniated disks, or masses that may be compressing the spinal cord. MRI is recommended if feasible and is especially useful if CT findings are discordant with symptoms and for surgical planning (Kebaish & Harris, 2020).

The majority of data regarding the imaging modalities used in diagnosing TSCI in LMICs come from Sub-Saharan Africa. Most patients received plain radiographs in those studies that reported diagnostic methods (71%–100%) (Bellet et al., 2019; Eaton et al., 2019). CT scans and MRIs are less commonly utilized. Reasons included lack of availability in the treatment facility or patient inability to pay for the diagnostic test. Between 7% and 59% of patients had a CT scan, and 41%–72% had an MRI (Ametefe et al., 2016; Leidinger et al., 2019). For reference, a 2019 survey of emergency medicine providers found that 99% and 97% of respondents in HICs reported access to in-hospital plain radiography and CT, respectively. Of respondents in LMICs, 91% reported access to in-hospital plain radiography, and 65% reported access to in-hospital CT (Alibhai, Hendrikse, & Bruijns, 2019).

Prehospital and acute management

Care provided during the first 24–48 h following a traumatic TSCI is critical and can significantly influence TSCI outcomes (Gélis et al., 2011). Prehospital management requires rapid evaluation, including measurement of vital signs and level of consciousness; initiation of injury management, spinal immobilization to preserve neurological function until long-term spinal stability is established, and control of bleeding, body temperature, and pain; and prompt and safe access to the healthcare system.

Prehospital care is underdeveloped in low-income countries. Emergency medical services are frequently inadequate or nonexistent. For example, in Tehran, Iran, only one-third of patients with spinal injuries are transported by emergency medical services (Sharif-Alhoseini & Rahimi-Movaghar, 2014). Similarly, in Botswana, only 20% of patients are transported by ambulance (Löfvenmark et al., 2015). Difficult terrain and transportation costs delay care, and patients may not arrive at a hospital for several days after their injury. Studies from Tanzania and Nepal reported approximately one-third of patients took greater than 2 days from injury to reach a hospital (Bellet et al., 2019; Dhakal et al., 2018; Lakhey et al., 2005). In Afghanistan, the average time to a hospital after sustaining TSCI was 3.4 days (Deconinck, 2003).

Due to cost and resource limitations in LMICs, spinal precautions are infrequently practiced in the prehospital setting. Among patients with cervical spine injuries in Nepal, only 36% arrived at the hospital with a cervical collar (Munakomi, Bhattarai, & Cherian, 2017). In India, up to 98% of TSCI patients are not adequately immobilized (Aleem et al., 2017; Dhamangaonkar, Joshi, Kumar, & Goregaonkar, 2013). A study from Malawi reported that 37% of patients with TSCI had cervical collars placed at some point during their hospitalization and that no other spinal braces were utilized (Eaton et al., 2019).

Treatment strategies

Management of spinal cord injuries is divided into phases. Acute phase management is based on Advanced Trauma Life Support (ATLS) principles, including prioritizing and treating life-threatening injuries to maximize survival, treating disabling injuries to minimize impairment, and limiting pain and suffering. Assessment should begin immediately upon arrival at the hospital and include: a medical history, signs and symptoms, neurological examination, radiological imaging, and laboratory testing (Bickenback, 2013). Signs and symptoms of spinal cord injury include weakness, sensory and motor deficits, bowel and bladder dysfunction, anatomical deformity, and localized tenderness.

Decisions about the best management strategy depend on the environment, available infrastructure, and surgical expertise. For TSCIs, there are risks and benefits to both nonoperative and surgical management. Many factors must be considered to determine the most appropriate management approach, including the level of injury, type of fracture, degree of instability, presence of neural compression, and impact of other concurrent injuries. Nonoperative management involves measures to immobilize the spine and to reduce dislocation with bed rest, traction of the spine, or the wearing of orthoses for 2–3 months. Indications for surgical management include spinal column stabilization and spinal cord decompression by reducing a dislocation or removing fracture fragments that cause neural compression.

Operative management of TSCI, within the first 48 h, has been associated with improved neurologic outcomes (Furlan, Noonan, Cadotte, & Fehlings, 2011). Nonoperative management of these injuries is associated with a fourfold increase in mortality than those with similar injuries managed operatively (Lessing, Lazaro, et al., 2020). Also, operative intervention is associated with early mobilization, better neurologic improvement, and higher return to wage-earning jobs (Lessing, Zuckerman, et al., 2020).

In LMICs, a high proportion of patients presenting with spinal cord injury do not undergo operative intervention. Studies have shown 0%, 30%, and 60% of TSCI patients undergo surgical intervention in Malawi, Nigeria, and Ghana, respectively (Eaton et al., 2019; Nwankwo & Uche, 2013). The primary reasons expressed in studies for nonoperative management or delays in surgical intervention are a paucity of neurosurgical workforce, lack of patient finances, delays in imaging access, and unavailability of operating room access (Nwankwo & Uche, 2013).

Globally, approximately 22.6 million new cases need neurosurgery consults annually, with 13.8 million persons requiring surgical intervention (Dewan Rattani, Baticulon, et al., 2019; Kanmounye et al., 2020). However, approximately 5.2 million neurosurgical cases go untreated, primarily due to lack of neurosurgical services and inadequate surgical workforce, with Africa bearing the lowest surgeon densities (Dewan, Rattani, Fieggen, et al., 2019). In 2018, the median workforce densities (neurosurgeons per 100,000 population) by WHO region were Americas (0.54), Africa (0.05), Eastern Mediterranean (0.34), Europe (0.99), South-East Asia (0.13), and Western Pacific (0.11) (Fig. 4) (Kanmounye et al., 2020). Approximately one neurosurgeon per 212,000 people is required to meet the healthcare demands from neurotrauma

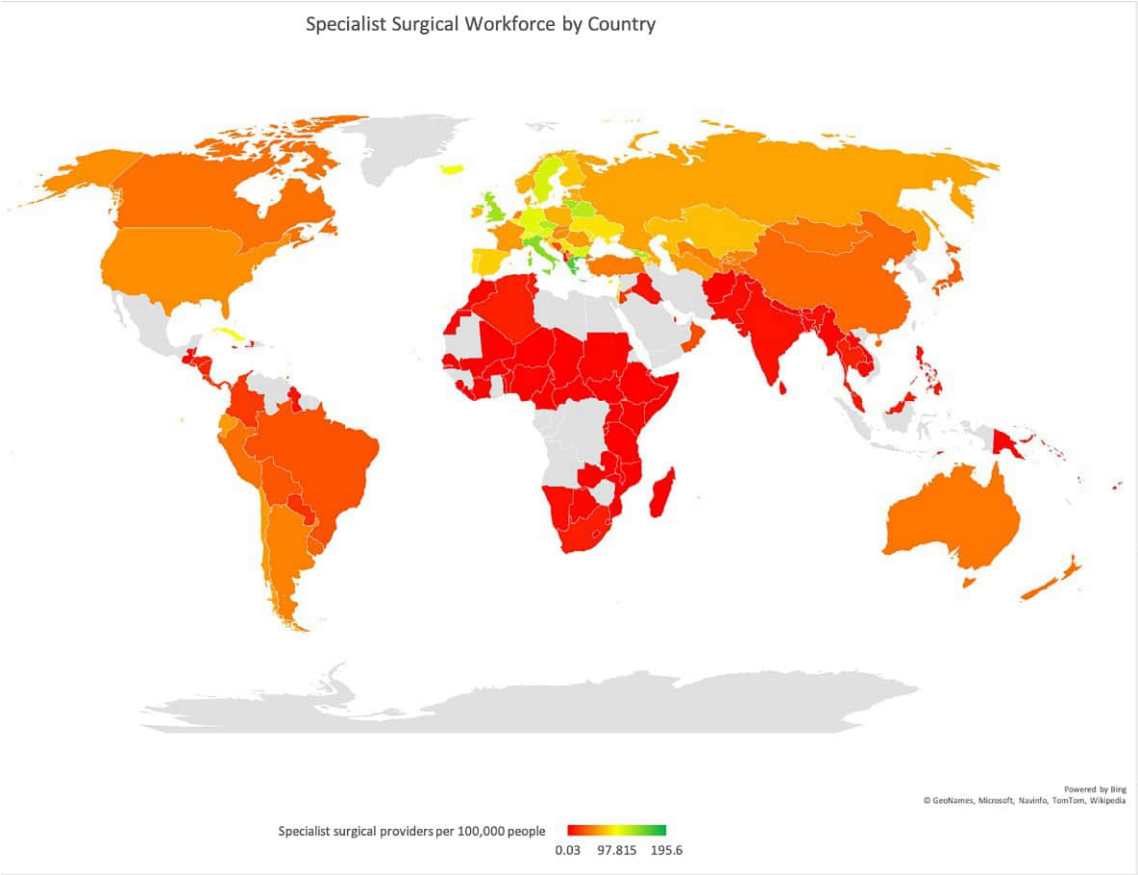

FIG. 4 Specialist surgical workforce by country. The figure displays the number of specialist surgical providers per 100,000 people (World Bank, 2018).

adequately, and an estimated 23,300 additional neurosurgeons globally are needed to address this significant deficit (Corley, Lepard, Barthélemy, Ashby, & Park, 2019).

Surgical care to patients and their families is often cost-prohibitive (James et al., 2019; Kumar et al., 2018). It is expected that patients and families must gather the funds to pay for the cost of surgical supplies, implants, or diagnostic radiology. High implant costs for spinal cord operative management can often lead to delay or deferment of operative treatment (James et al., 2019; Kumar et al., 2018). A Tanzanian study determined nonoperative management costs 212 USD per patient compared to 731 USD per patient for operative management (Lessing, Zuckerman, et al., 2020). However, operative management was determined to be cost-effective as the incremental cost per disability-adjusted life years averted was 112–158, 47–67, 50–71, 41–58 USD for quadriplegic, paraplegic, neurologic improvement, and neurologically intact patients, respectively (Lessing, Zuckerman, et al., 2020).

Ancillary support is also challenging in low-resource environments for patients needing treatment for spinal cord injuries. There is a lack of intensive care unit (ICU) beds and respiratory, physical, and occupational therapy. In the United States, the ICU bed density is approximately 20–32 beds per 100,000 population, compared to 5 beds per 100,000 in the United Kingdom, 2.8–4.6 beds per 100,000 in China, and 0.34–1.57 beds per 100,000 population in India (Gooch & Kahn, 2014; Murthy & Wunsch, 2012). There is a lack of critical care data in Sub-Saharan Africa. The estimated ICU bed density in Malawi is 0.1 beds per 100,000 population (Fig. 5).

Post-acute medical care and rehabilitation

Appropriate medical care and rehabilitation can prevent TSCI complications and help patients achieve a meaningful life. Rehabilitation, defined as a "set of measures that assist individuals in achieving and obtaining optimal functioning in the interaction with their environments" (World Health Organization, 2011), should commence in the acute phase for people

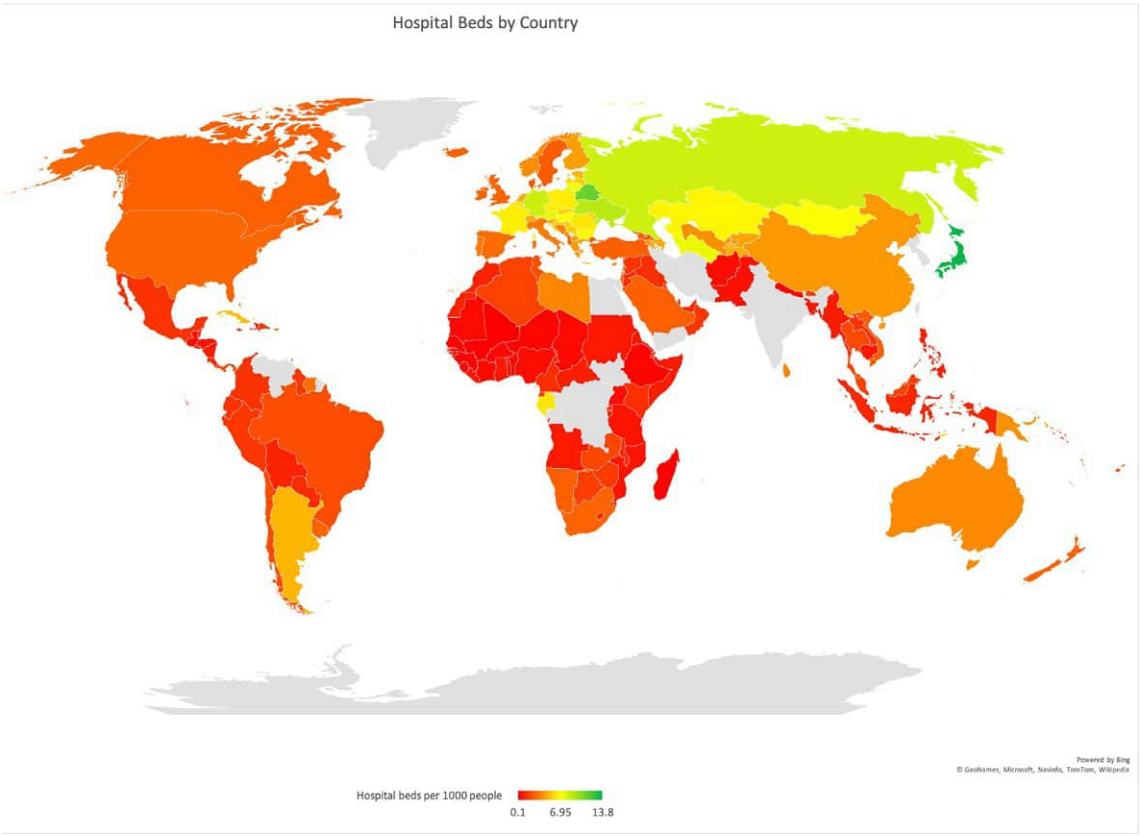

FIG. 5 Number of hospital beds by country. This figure shows the number of hospital beds per 1000 people by country (World Bank, 2015).

with TSCI, continue to be available to promote functioning, and be available in a range of different settings from the hospital through to the home and community environments.

Loss of normal bladder function is one of the most significant consequences for people who have sustained TSCIs. Inadequate management of bladder function leads to secondary complications such as UTIs, urinary retention, incontinence, stones in the kidneys and urinary tract, and reflux of urine (Consortium for Spinal Cord Medicine, 2006). These urinary complications can result in renal failure (Wolfe et al., 2010).

Neurogenic bowel is a common condition following TSCI. It is associated with many gastrointestinal problems, including poor colonic motility, prolonged bowel transit time, chronic constipation, abdominal distension, and fecal incontinence (Correa & Rotter, 2000). People with TSCI who experience a neurogenic bowel are often afraid of possible bowel incontinence, which can significantly impact an individual's ability to return to former social roles and activities (Krassioukov, Eng, Claxton, Sakakibara, & Shum, 2010; World Health Organization, 2011). Adequate management of bowel function can be challenging where resources are limited (Yasmeen, Rathore, Ashraf, & Butt, 2010).

Rehabilitation should aim to help people overcome these limitations by improving trunk and limb function, modifying the person's immediate environment, and providing assistive devices and other reasonable accommodations to enable individuals to continue family and work roles. The reality in most LMIC is that access to rehabilitation is somewhat limited, and most patients are ultimately cared for at home in the community. In a study in rural Uganda, impaired sexual (90%) and bowel/bladder function (80%), depression and chronic pain (85%), skin break-down, and urinary infections (57%) recognized complications of long-term TSCI (Stothers, Macnab, Mukisa, Mutabazi, & Bajunirwe, 2017). Major problems articulated were lack of care for patients living at home, lack of support for family caregivers, and limited aids to living, including wheel-chairs and crutches. Locally made walking aids are prevalent, but most patients rely on family members for their mobility.

In LMICs, infections and septicemia caused by urinary tract complications and pressure sores are still the leading cause of death for people with TSCI (Gosselin & Coppotelli, 2005; Hoque, Grangeon, & Reed, 1999). In Zimbabwe, 7% of individuals with TSCI died from septicemia due to pressure sores while being hospitalized (Correa & Rotter, 2000). With regular turning to relieve pressure points and proper nursing care, pressure sores could be prevented.

Life expectancy for individuals with TSCI in less-resourced settings is shorter than for the average population and persons with TSCI in HICs. Septicemia resulting from urinary tract infections and pressure sores was still the leading cause of death and had the most significant impact on life expectancy and daily life among individuals with TSCI. The findings confirm that individuals with TSCI and their families in low-income settings face substantial challenges in their everyday life because of limited financial, medical, social, and technical support. Poverty has an even more significant impact on people with TSCI in low-income countries, contributing to individual suffering and a high mortality rate due to limited access to rehabilitation services, including appropriate wheelchairs and medical treatment for complications, such as infections, pressure sores, and respiratory problems, common to people with TSCI.

Appropriate and timely medical care and rehabilitation can significantly reduce mortality, morbidity, and disability in TSCI patients. Access to specialized and health care can lead to better outcomes and a productive and enjoyable life for people with TSCI.

Applications to other areas of neuroscience

The two most common causes of TSCI falls, and road traffic injuries (RTIs) are also the two most common causes of traumatic brain injury (TBI) (James et al., 2019). Co-occurrence of TBI and TSCI is common, especially in cervical TSCI (Macciocchi, Seel, Thompson, Byams, & Bowman, 2008). Studies that have specifically evaluated this co-occurrence found that patients who sustain TSCI have a 16%–60% chance of sustaining a TBI (Macciocchi et al., 2008). Moreover, there is evidence that TBI in TSCI patients is significantly underdiagnosed in up to 60% of cases, which may be even higher in LMICs that have limited access to resources such as imaging and neuropsychological testing (Sharma, Bradbury, Mikulis, & Green, 2014). Not surprisingly, patients with dual diagnoses experience worse functional outcomes than patients with TSCI alone (Garlanger, Beck, & Cheville, 2018).

Recognition of this relationship has several important implications. First, efforts to reduce traumatic mechanisms can be expected to minimize TSCIs and TBIs by improving road safety and working conditions. Second, a high index of suspicion is essential for patients who are at risk for TBI, especially in low-resource settings with limited access to diagnostic adjuncts. Lastly, patients with dual diagnoses require special consideration when planning for discharge from a hospital or rehabilitation center. TSCI alone presents a massive challenge in low-resource settings. A concurrent TBI will severely impact functional independence and community reintegration.

Key facts of global traumatic spinal cord injury epidemiology and etiology

- The global incidence is between 250,000 and 1 million annually.
- Males are more commonly affected than females, and at least two-thirds of patients are males in most countries.
- In high-income countries (HICs), TSCIs occur in a bimodal age distribution. In low- and middle-income countries (LMICs), however, TSCIs predominantly affect younger patients.
- The two most common causes of TSCIs worldwide are falls and road traffic injuries (RTIs).
- In areas where active armed conflict is common, such as the Middle East, violence is the leading cause of TSCIs.

Summary points

- The global incidence of TSCI is between 250,000 and 1 million annually.
- Males are more commonly affected than females worldwide.
- The two most common causes of TSCI are falls and road traffic injuries (RTIs).
- There is significant global variation in the distribution of spinal cord injury level and severity.
- Patients in LMICs experience significant delays to care following TSCI.
- Due to the lack of resources in LMICs, a high proportion of patients with TSCI who would benefit from surgical treatment do not undergo operative management.
- Rehabilitation services in LMICs are limited, and patients in these settings have difficulty gaining independence and preventing long-term complications of TSCIs.
- In LMICs, infections and septicemia caused by urinary tract infections and pressure sores are the leading cause of death for people with TSCIs.
- Life expectancy for individuals with TSCIs in LMICs is lower than that of the average population and lower than that of individuals with TSCI in HICs.

Chapter 2

Biomechanics and patterns of spine injuries associated with spinal cord injury

Salomón Flórez-Jiménez, Étienne Bourassa-Moreau, Jean-Marc Mac-Thiong, and Gilles Maurais
Department of Spinal Surgery, Sacré-Coeur Hospital of Montreal, Université de Montreal, Montréal, QC, Canada

List of abbreviations

CCS Central cord syndrome
PLC Posterior ligamentous complex
TSCI Traumatic spinal cord injury

Introduction

Worldwide, approximately 30 million individuals live with a traumatic spinal cord injury (TSCI), and about 1 million new cases of TSCI occur annually, and these numbers are expected to increase in view of population growth. Annually, 150,000 spine fractures are treated in the United States. Among those, close to 20% are associated with spinal cord injury (SCI) (Buchowski, Kuhns, Bridwell, & Lenke, 2008). A spinal fracture and/or dislocation occurs in about 65% of all TSCI.

TSCI contributes to a considerable burden on patient's lives because of lifelong functional disabilities and major psychosocial challenges. Accordingly, the severity of the spine injuries is usually associated with the severity of the SCI, in line with increased burden of healthcare resource utilization. Although management of the underlying spine injuries further contributes to the economic burden of TSCI, it is strongly influencing the clinical outcomes of patients.

TSCIs are most often due to a traumatic event, mainly falls and motor vehicle accidents. While motor vehicle accidents remain the most common cause of TSCI, there is an increasing incidence of TSCI due to low-energy trauma such as falls (Chen, He, & DeVivo, 2016; Pickett, Campos-Benitez, Keller, & Duggal, 2006).

Because of physiological changes due to aging, elderly individuals are particularly at increased risk of sustaining a TSCI from low-energy trauma such as a fall from their height.

In keeping with the aging of the general population, a demographic shift is observed toward older TSCI patient's population (Ahn et al., 2017) with pre-existing spondylotic spinal stenosis and without significant traumatic spinal instability.

Understanding the biomechanics and patterns of the common types of spine injuries associated with SCI is central to the management of individuals with TSCI, and will be featured in this chapter.

Pathogenesis of TSCI: The critical role of spine biomechanics

Several studies (Al-Habib et al., 2011; Wagnac et al., 2019; Wilson, Cadotte, & Fehlings, 2012) demonstrated the importance of the mechanism and level of energy of the traumatic event as predictors of the severity of TSCI. When compared with low-velocity trauma (e.g., fall from standing height), high-velocity mechanisms of trauma (e.g., motor-vehicle accidents) more often result in increased spinal cord damage, particularly in the white matter (Mattucci et al., 2019). The mechanism and level of energy of the trauma are only moderately associated with the outcomes, because they only partially reflect the level of energy that was actually transferred to the spinal cord during the trauma. During the trauma, the primary injury to the spinal cord occurs due to the physical insult and local energy transferred to the spinal cord, thereby causing direct damage to neural tissues and its blood vessels. It is believed that the morphological pattern of the spine injury is a better reflection of the underlying dynamics and local energy sustained by the spinal cord during the trauma than the mechanism of trauma and global level of energy (Goulet, Richard-Denis, Petit, Diotalevi, & Mac-Thiong, 2020). During the trauma, energy is transferred to the spinal cord by direct or indirect mechanisms originating from the spine injury.

Diagnosis and Treatment of Spinal Cord Injury. https://doi.org/10.1016/B978-0-12-822498-4.00002-6

Direct injury occurs from contusion of the spinal cord by vertebral bone and soft tissues (intervertebral disc and/or ligaments) in direct contact with the spinal cord.

Indirect injury to the spinal cord results from the motion (e.g., flexion, hyperextension, axial compression, distraction, dislocation, etc.) between spinal elements during the trauma, causing excessive tension, shear, torsion, compression, and/or bending loads on the spinal cord.

The type of loads sustained by the spinal cord will influence the extent of tissue damage (Chen et al., 2016), contributing to the heterogeneity of the clinical outcomes observed following a TSCI (Mattucci et al., 2019). Contusion causes a relatively localized damage, as opposed to dislocation (causing mainly shear stress) and distraction which result in more asymmetrical damage that can extend further rostrally and caudally (Chen et al., 2016).

The acute surgical management is critical in TSCI patients and serves two purposes: neurological decompression and spinal stabilization. Neurological decompression entails removal of bone, blood, and disco-ligamentous structures that impinges the spinal cord, whereas spinal stabilization is achieved by spinal instrumentation rigidly connecting the unstable segments of the spine. Acute surgery ultimately aims at limiting the secondary injury to the spinal cord. The pattern of spine injury contributes to the secondary injury of the spinal cord through direct and indirect mechanisms. The residual compression of the spinal cord for example from the typical vertebral bone fragment retropulsed in the spinal canal with thoracolumbar burst fractures directly exerts loads on the spinal cord. In parallel, residual misalignment or instability between spinal elements can also exert undue loads on the spinal cord through an indirect mechanism, further contributing to the secondary injury of the spinal cord if it has not been addressed properly. Careful and prompt assessment of the clinical stability is therefore key after a TSCI.

In line with the definition by White 3rd, Johnson, Panjabi, and Southwick (1975), we define traumatic spinal instability to be the loss of the ability of the spine to maintain normal alignment and motion between spinal segments in such a way that a secondary injury to the spinal cord will not occur.

Patterns of spine injuries associated with spinal cord injuries

TSCI can be associated with a stable or unstable spine, and we suggest that TSCI should be categorized accordingly to guide its management.

Traumatic spinal cord injury in a stable spine

Different terminologies have been used previously to describe TSCI not associated with overt spinal instability. The term SCIWORA (Spinal Cord Injury Without Radiographic Abnormality) was proposed by Pang and Wilberger Jr. (1982) in 1982 to describe TSCI occurring in children without evidence of spine injuries such as fracture or dislocation on plain radiographs or tomography. Given the inherent elasticity of the vertebral column in children, they suggest that the vertebral column can deform in flexion, hyperextension or distraction in such a way that the spinal cord can be injured without concomitant damage of the vertebral column. SCIWORA more frequently involves the cervical spinal cord because spinal mobility is greater in the cervical than the thoracic and lumbar spine. In the adult population, SCIWORA has also been used to describe TSCI associated with underlying spondylotic changes, spinal stenosis, ossification of posterior longitudinal ligament, ligamentous abnormalities, and/or traumatic disc herniation (Asan, 2018; Boese et al., 2016; Boese & Lechler, 2013; Gupta et al., 1999), in the absence of fracture or dislocation. Many authors (Como et al., 2012; Dreizin et al., 2015) warn about the misapplication of the term SCIWORA in adults considering that these patients will commonly have underlying canal stenosis and significant degenerative changes—which are radiographic abnormalities per se—and instead propose the use of the term SCIWOCTET (Spinal Cord Injury Without Computed Tomography Evidence of Trauma) or SCIWORET (Spinal Cord Injury Without Radiographic Evidence of Trauma) in these patients.

For the cervical spine, proper identification of TSCI with a stable spine is important because they are typically associated with improved recovery (Paquet et al., 2018). While the presence or absence of radiographic/tomographic findings can help to understand the pathomechanism of the injury and guide treatment, the central aspect to SCIWORA, SCIWORET, and SCIWOCTET is that they usually are not associated with overt spinal instability. For these conditions, the spinal cord is at higher risk of injury either due to the altered biomechanics of the spine or to the decreased space available for the spinal cord. The current authors believe that the overarching concept for these aforementioned terms is the absence of spinal instability, and that these terms should be used with caution because they underestimate the importance of spinal trauma and biomechanics in the context of TSCI. Radiological evidence of trauma can include a wide range

of findings, and should not be interpreted without consideration of the spinal stability. The authors instead propose to use the term TSCI with a stable spine in order to account for the biomechanical and surgical aspects involved in the management of TSCI. Indeed, TSCI with a stable spine does not preclude the presence of minor spinal injuries such as spinous process fractures that do not impair the clinical stability of the spine and do not require surgical stabilization.

In adults, underlying degenerative changes are usually observed, but the literature does not provide specific outcome predictors based on the evaluation of the underlying spondylosis.

Animal models repeatedly showed a strong correlation between the amount of spinal cord compression and severity of the neurological impairment. However, in adult trauma patients the correlation between cord compression observed on MRI and the neurological impairment remains unclear. Interestingly, normal aging of the spine commonly implies degenerative changes that cause reduction of the diameter of the spinal canal called spinal stenosis, especially at the cervical level. Literature does not provide specific outcome predictors based on the evaluation of the underlying spondylosis. In a population of adult low-velocity cervical trauma—CCS—Aarabi et al., 2011 found a somewhat counterintuitive association between maximal cord compression on MRI and neurological recovery.

The CCS is a common clinical syndrome observed after a cervical TSCI and is typically observed in the presence of a stable spine. It has been described initially by Schneider, Cherry, and Pantek (1954) and is characterized by a disproportionate greater motor impairment in the upper extremities and varying degree of bladder dysfunction and sensory loss. The central cord syndrome is mainly prevalent in the elderly population with pre-existing spondylotic cervical stenosis (McKinley, Santos, Meade, & Brooke, 2007; Molliqaj, Payer, Schaller, & Tessitore, 2014). The mechanism of trauma typically involves a fall from someone's height with cervical hyperextension. During hyperextension of the cervical spine, spinal cord damage associated with the central cord syndrome results from posterior compression from inward bulging of the ligamentum flavum and from anterior compression from marginal osteophytes and/or bulging discs (Schneider et al., 1954). The greater impairment in the upper extremities results from the injury to the spinal gray matter and lateral corticospinal tracts (Collignon, Martin, Lenelle, & Stevenaert, 2002). More specifically, it is believed that the predominant involvement of the upper extremities is due to the somatotopic arrangement of the lateral corticospinal tracts, such that the medial (more central) portion of the corticospinal tract controlling upper extremity motor function sustains a greater injury than the lateral portion controlling lower extremity motor function (Schneider, Thompson, & Bebin, 1958). However, this hypothesis has been challenged by different authors who observed a uniform damage to the lateral corticospinal tract, suggesting that motor fibers descending to the upper and lower extremities are interlaced (Nathan & Smith, 1955; Quencer et al., 1992).

In a finite-element analysis, Bailly et al. suggest that the presence of hypertrophic ligamentum flavum induced specific stress and strain distributions consistent with previous histologic findings related to central cord syndrome. The presence of a disc bulging alone was not associated with such a pattern, but when combined with hypertrophic ligamentum flavum, increased the overall level of stress and strain in the lateral corticospinal tract (Fig. 1)

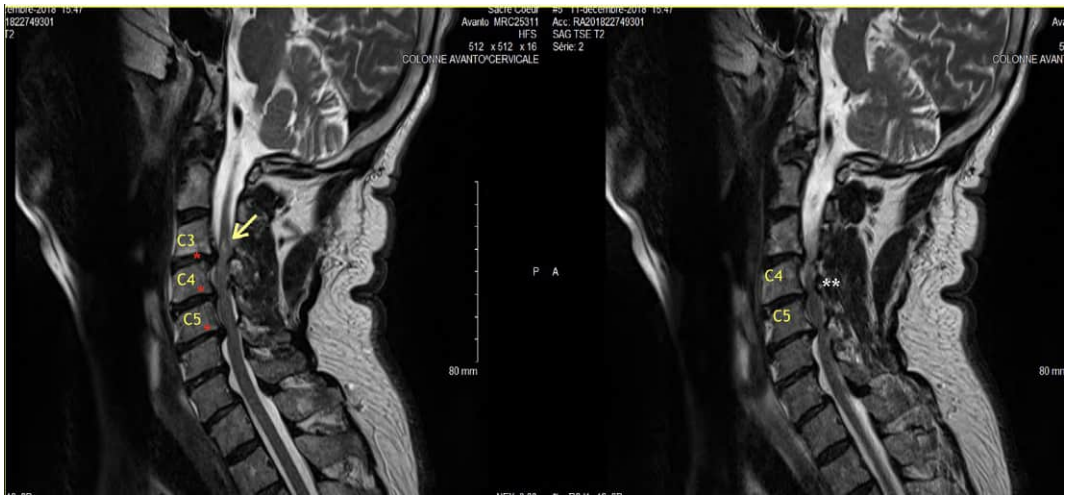

FIG. 1 Hyperextension cervical trauma in a stable spine with degenerative changes. CCS. (*) red asterisks, Bulging disc C3–C4, C4–C5, C5–C6. (**) White asterisks, thickened ligamentum flavum multilevel mainly C4–C5. Yellow arrow showing spinal cord edema and hypersignal in C3 level.

Traumatic spinal cord injury in an unstable spine

While TSCI in a stable spine occurs predominantly at the cervical level due to the increased range of motion and frequent preexisting canal stenosis, unstable injuries occur commonly at all spinal levels. The neurological level of injury strongly relates to the neurological recovery, and it is common to distinguish between high cervical (C1–C4), low cervical (C5–C8), thoracic (T1–T10), and thoracolumbar (T11–L2) TSCI (Dvorak et al., 2014). These categories account for the functional activity of the spinal cord, including breathing, upper versus lower extremity function, trunk control, and bowel/bladder function. However, other anatomical and morphological criteria should also be considered to further delineate the level of injury and characterize the trauma biomechanics when classifying and managing the unstable spine associated with TSCI.

There are three basic categories or types used in a similar manner to the AO thoracolumbar fracture classification system to describe primary injury morphology. The "Type A" injuries are fractures that result in compression of the vertebra with intact tension band. "Type B" injuries include failure of the posterior or anterior tension band through distraction with physical separation of the subaxial spinal elements while maintaining continuity of the alignment of the spinal axis without translation or dislocation. "Type C" includes those injuries with displacement or translation of one vertebral body relative to another in any direction; anterior, posterior, lateral translation, or vertical distraction. Injuries are first classified by their level and either C, B, or A in this order (Vaccaro et al., 2016).

Cervical spine injuries (C0–C7)

TSCI with an unstable spine are highly prevalent in the cervical spine for different reasons. The cervical spine is vulnerable to several types of trauma mechanisms, including motor vehicle accidents, diving, sports injuries, and falls. When compared to the thoracic and lumbar spine, the bony elements in the cervical spine are smaller and the disco-ligamentous structures are weaker so that they are more exposed to injuries.

In line with the demographic shift to an older population, the increasing prevalence of cervical degenerative changes and pre-existing spondylotic stenosis increases the likelihood to sustain a TSCI in association with a cervical trauma.

Upper cervical spine injuries (C0–C2)

TSCI following traumatic spine injuries occurring at the occipito-cervical or atlanto-axial level are highly distinct from subaxial injuries due to the increased risk of mortality and poor recovery. It is thought that between 8% and 19% of fatal cervical spine injuries result from occipito-cervical dislocation (Bucholz, Burkhead, Graham, & Petty, 1979). In addition, occipito-cervical and atlanto-axial levels have a highly distinct bony/soft tissue anatomy and biomechanical behavior, which require particular attention for evaluation and management. The spinal canal is also particularly large at these levels; it is widest between the C1 and C3 levels (AP diameter 16–30 mm) and progressively narrows caudally (14–23 mm).

Occipito-cervical dislocation is associated with high mortality rates because a high-energy trauma—and high level of energy transferred to the spinal cord—is required to damage the strong ligamentous structures at the occipito-cervical junction, which comprise the tectorial membrane and alar ligament (Alker et al., 1975).

TSCI is seen infrequently with isolated C1 fracture (Lee & Woodring, 1991). A TSCI occurs when the transverse ligament is torn and atlanto-axial instability occurs. The mechanism of SCI is similar to that occurring with isolated rupture of the transverse ligament or odontoid fracture: the spinal cord will be compressed between the posteriorly displaced odontoid and the posterior arch of C1.

Subaxial cervical spine injuries (C3–C7)

The Spinal Trauma Study Group (Vaccaro et al., 2007) provided new insight on the morphological features of subaxial cervical trauma that need to be considered in TSCI, through the proposal of a novel classification system. In line with previous studies (Chen et al., 2016), they consider that the severity and outcome of TSCI depend on the morphology of the lesion, which results in different loading conditions in the spinal cord. Based on their concept, we propose that TSCI with unstable subaxial cervical spine be classified following this increasing order of severity:

(1) Compression injury without involvement of the posterior vertebral wall.
(2) Burst injury with involvement of the posterior vertebral wall.
(3) Distraction injury such as a hyperextension injury involving rupture of anterior longitudinal ligament and intervertebral disc or a flexion-distraction injury involving disruption of posterior ligaments and facet capsules.
(4) Translation/rotation injury which is typical of bilateral facet dislocation.

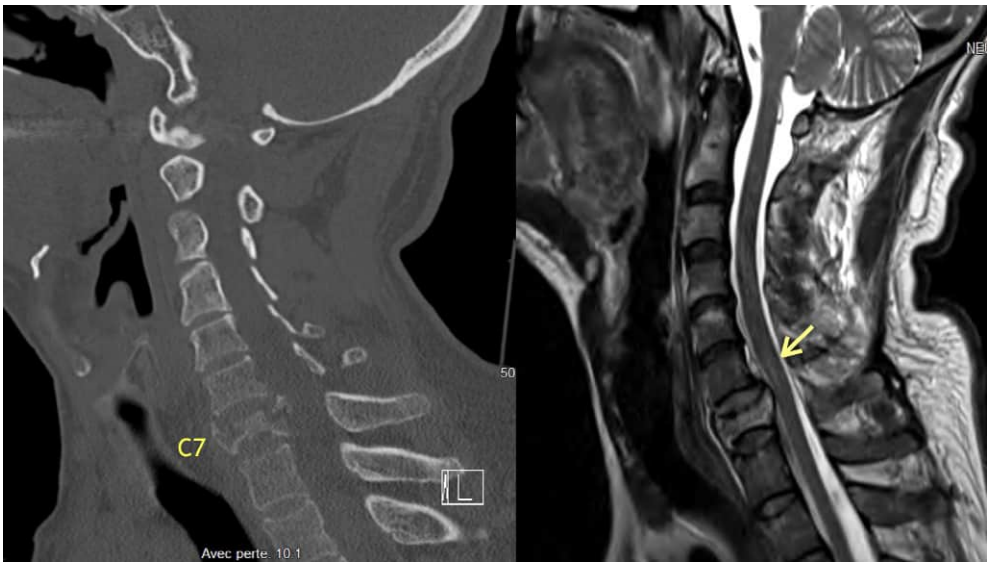

FIG. 2 Burst fracture of C7 and significant energy transferred to the spinal cord from retropulsion of the posterior wall into the spinal canal causing spinal cord edema (yellow arrow).

TSCI is unlikely with a compression injury sparing the posterior vertebral wall, unless significant kyphosis occurs (Yokota et al., 2019). A TSCI is more likely with burst fractures when significant energy is transferred to the spinal cord from retropulsion of the posterior wall into the spinal canal (Fig. 2)

Hyperextension injury causes distraction of the spinal cord that can lead to neural damage. In addition, spinal cord damage can result from inward bulging of the ligamentum flavum in the presence of a spondylotic spine, by a mechanism similar to that described above for cervical TSCI in a stable spine. A hyperextension injury—and less frequently a translation injury—is typically observed with a cervical TSCI in patients with a rigid spine (e.g., ankylosing spondylitis, diffuse idiopathic skeletal hyperostosis or ossification of the posterior longitudinal ligament). For these patients, the presence of an epidural hematoma causing the SCI should also be ruled out (Fig. 3)

Facet dislocations are most common in the subaxial cervical spine because a lesser magnitude of force is required to produce the dislocation, as compared to the thoracic and lumbar spine (Holdsworth, 1970). This is mainly due to the

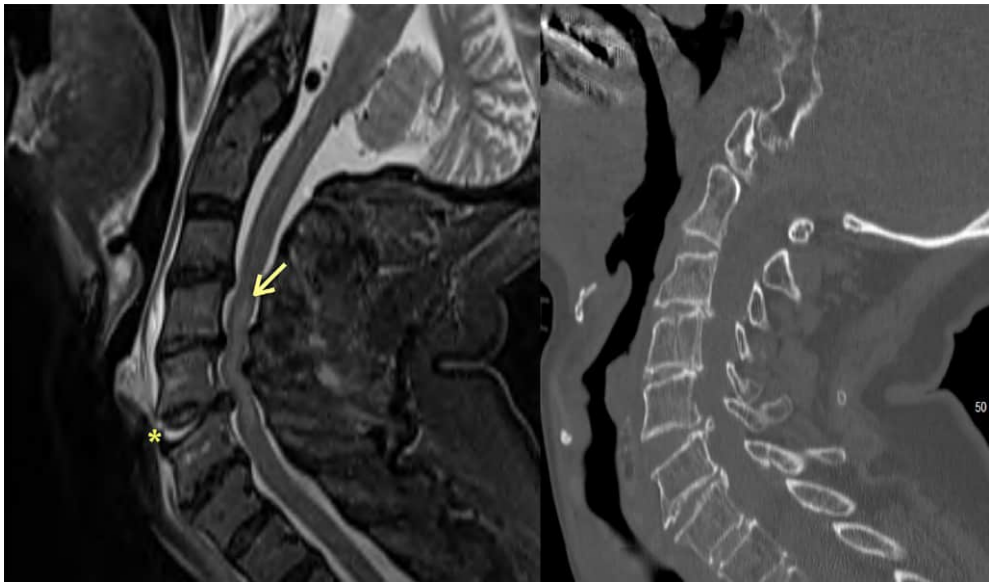

FIG. 3 Hyperextension injury in a mobile spine ct and irm, showing disc rupture (yellow asterisk) and spinal cord edema (arrow).

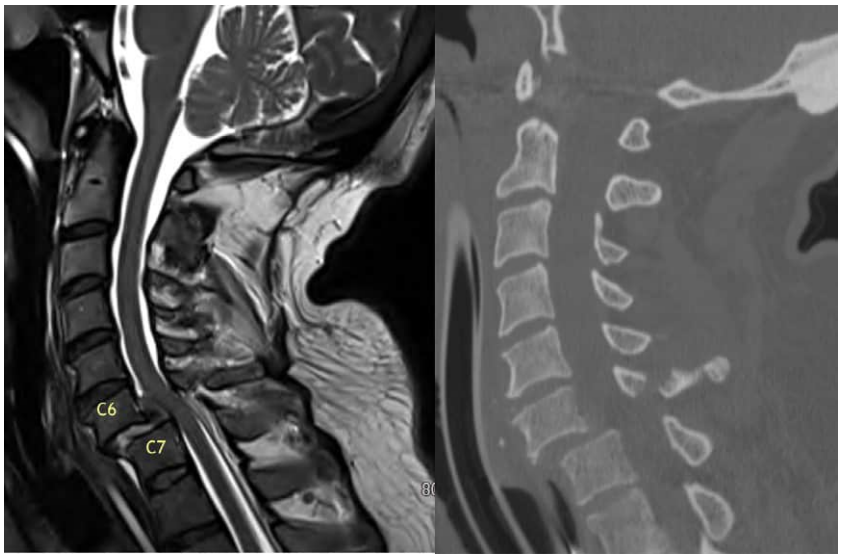

FIG. 4 Cervical dislocation C6–C7.

increased mobility, distinctive orientation of the superior articular facets (Ebraheim, Patil, Liu, Haman, & Yeasting, 2008), and smaller osseous and ligamentous structures of the cervical spine. Facet dislocation typically occurs as a result of a hyperflexion injury and is commonly associated with SCI (Sekhon & Fehlings, 2001; Tator, 1983).

During the trauma, the primary injury to the spinal cord results from the distraction of the spinal cord posteriorly as well as the resulting translation and/or rotation between dislocated vertebrae causing shear stresses on the spinal cord. After the trauma, a secondary injury to the spinal cord is accentuated by the shear and compression loading from residual translation and/or rotation between vertebrae, which needs to be managed by surgery.

Wilson et al. showed that cervical dislocation is more frequently associated with severe neurological deficit and high-energy trauma mechanisms, and results in a diminished potential for recovery (Wilson et al., 2013) (Fig. 4)

Thoracic spine injuries (T1–T10)

The pathomechanism and outcome of thoracic injuries significantly differ from cervical injuries because of the inherent stability provided by the thoracic cage (i.e., ribs and sternum). Each thoracic vertebra has a diarthrodial articulation with a rib on each side, thereby increasing the stability of the thoracic spine and potentially decreasing the incidence of degenerative changes since reduced mobility.

The thoracic facet joints are aligned with the coronal plane to allow for axial rotation. The ratio of the canal size to the spinal cord size is relatively small in the thoracic spine, which increases the risk of neurologic injury even with small amounts of canal intrusion.

The tenuous blood supply (critical watershed area) in the upper thoracic region also exposes the spinal cord between T4 and T10 at increased risk of SCI with a spine trauma.

In aging individuals with osteoporosis, a minor trauma can cause a compression fracture in the thoracic spine, usually below T4 and most often at the thoracolumbar region. However, a TSCI is rarely seen with osteoporotic compression fractures, even in the presence of a marked kyphotic deformity. When a TSCI occurs after minor trauma in an osteoporotic patient, it is usually secondary to a burst fracture with a retropulsed fragment into the spinal canal, and the onset of neurological deficit is typically gradual rather than acute. For patients with a rigid spine (e.g., ankylosing spondylitis and diffuse idiopathic skeletal hyperostosis), a hyperextension or translation spine injury should be suspected in the presence of a TSCI at the thoracic level, even if a minor trauma has occurred.

More often, thoracic TSCI results from high-energy trauma mechanisms. Thorough clinical and radiological evaluation of the thoracic cage should be performed to assess the stability of the spine injury because the great majority of thoracic TSCI will involve an associated disruption of the thoracic cage.

Associated fractures of the sternum and/or ribs should raise the suspicion for severe spinal instability. Because most thoracic TSCI result from high-energy trauma, the initial neurological deficit is usually severe, and the prognosis is often poor (Bourassa-Moreau et al., 2016; Zariffa et al., 2011) (Fig. 5).

FIG. 5 Complete injury SCI, dislocation, and chest trauma. Complex comminuted fracture with lateral dislocation of the D3–D4 vertebrae and discontinuity of the spinal canal. Multiple bilateral rib fractures, Right hemothorax. Extensive right subpleural pulmonary contusion and minimal right apical pleural detachment.

Thoracolumbar spine injuries (T11–L2)

The thoracolumbar junction between T11 and L2 is the most frequent site for TSCI in an unstable spine for both osteoporotic and nonosteoporotic individuals.

There is an increased stress concentration in this region because it is a transition zone from the stiff thoracic spine/cage and the mobile lumbar spine. The straight alignment of the thoracolumbar region between the supra-adjacent thoracic kyphosis and subjacent lumbar lordosis also increases the transfer of axial compression loads through this region and resulting risk of compression and burst fractures.

While compression fractures are usually not associated with TSCI, thoracolumbar burst fractures can be associated with a TSCI due to a bony fragment retropulsed into the spinal canal and compressing the spinal cord.

In the presence of a TSCI, determining the morphological pattern of the thoracolumbar fracture seems particularly useful to characterize the severity of the injury and the prognosis for neurological recovery. Different authors (Keynan et al., 2006; Martineau, Goulet, Richard-Denis, & Mac-Thiong, 2019) propose that the energy directly transferred to the spinal cord during the trauma is strongly related to the local morphological pattern of thoracolumbar fractures, as opposed to the global level of energy or mechanism of the trauma.

The morphological pattern of thoracolumbar injury also provides insight into the dynamics of the SCI during the trauma, more so than the residual compression of the spinal cord after the trauma from the retropulsed fragment.

It is well recognized that the dynamic spinal canal encroachment during the trauma is significantly greater than the static canal encroachment seen on posttrauma imaging. Accordingly, the degree of canal occlusion observed after the trauma is not related to the neurological outcome (Boerger, Limb, & Dickson, 2000; Herndon & Galloway, 1988; Mohanty & Venkatram, 2002).

Goulet et al. have shown that posterior translation of the posteroinferior wall of the vertebral body, presence of comminution of the bony fragment retropulsed into the spinal canal and complete lamina fracture were strongly associated with neurological recovery.

These findings suggest that these morphological features—characterizing damaged bony structures directly in contact with the spinal cord—should be assessed routinely in TSCI patients to estimate the local level of energy transferred to the spinal cord and the prognosis for recovery. Conversely, vertebral body comminution, local/segmental kyphosis, and the degree of canal compromise were not associated with the neurological outcome. In their finite-element computational simulation of TSCI for thoracolumbar burst fractures, Diotalevi et al. tested 16 typical clinical scenarios with varying degree of comminution, velocity, and displacement of the bony fragment retropulsed into the spinal canal, as well as the presence or absence of a fracture of the posteroinferior vertebral body wall.

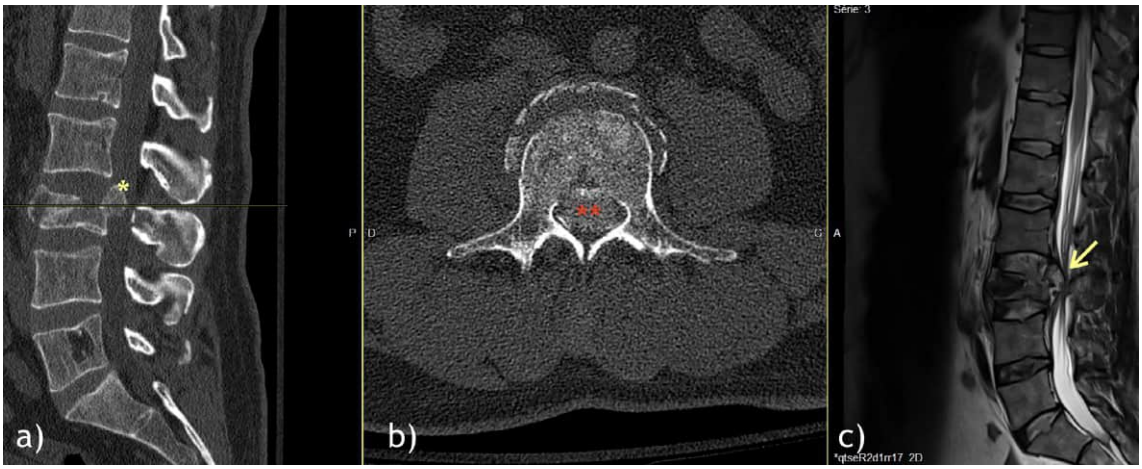

FIG. 6 Burst T3. (A) Translation posterior wall. [yellow asterisk (*)] (B) comminution of the fragment and lamina fracture [red asterisks (**)]. (C) MRI showing compression and cord edema (Yellow arrow).

They observed that the velocity of the retropulsed fragment was the most important factor influencing the stresses and strains on the spinal cord, followed by a fracture of the posteroinferior vertebral body wall and sagittal rotation of the retropulsed fragment (Diotalevi et al., 2020) (Fig. 6)

The Spinal trauma Study Group put a strong emphasis on the assessment of the posterior ligamentous complex (PLC) (supraspinous ligament, interspinous ligament, ligamentum flavum, and facet joint capsules) to further assess the stability of thoracolumbar spine injuries (Vaccaro et al., 2006). Rupture of the PLC entails a poor prognosis for healing because, unlike bone fracture, ligaments do not recover its pretrauma tensile strength after complete rupture.

Although the loss of integrity of PLC is a crucial element for surgeons to determine indication for surgery in thoracolumbar trauma, it remains to be defined whether injury to the PLC is associated with the occurrence a severity of TSCI.

Flexion-distraction spine injuries most often result from falls, car accident (seat belt injury), and unrestrained vehicle accidents (Wagnac et al., 2019). It is estimated that a small number (about 10%–15%) of flexion-distraction injuries in the thoracolumbar spine will lead to a SCI through a mechanism of distraction of the spinal cord. On the opposite, translation/rotation spinal injuries in the thoracolumbar spine typically result from a high-energy trauma mechanism and lead to severe TSCI due to the high shear stresses causing primary and secondary damage to the spinal cord. In the AO classification the type C injuries are translational injuries in any axis. No further subdivision is necessary since all Type C injuries are highly unstable due to separation, displacement, or translation of 1 vertebral body (or elements of it) relative to another in any direction.

Applications to other areas of neuroscience

Here we reviewed the basic biomechanical concepts of traumatic spinal cord injuries associated with spine injuries. We have also reviewed the local mechanisms by which the spinal cord is damaged during traumatic events, and we describe the interactions between spinal osteoligamentous elements and the spinal cord during and after the trauma.

The knowledge transferred in this chapter will help neuroscientists to better understand and study the primary and secondary spinal cord injuries occurring after a trauma. This work also underscores the importance of combining clinical and biomechanical knowledge for assessing and treating individuals following a traumatic SCI. For example, we have highlighted the relevance of using computational models for simulating and investigating traumatic spinal cord injuries. The concepts presented in this chapter could be applied for designing new preclinical models of traumatic SCI, or for planning on innovating research protocols. It is becoming clear that combining expertise in neurosciences and biomechanical engineering is key in the development of a more comprehensive understanding of traumatic spinal cord injuries in the future.

Mini-dictionary of terms

Traumatic spinal cord injury in a stable spine: SCI that causes neurological compromise and in the images there is no fracture or unstable injury, generally called CCS or SCIWORA.

Spinal cord distraction: Structural alteration in the white matter, sparing the most myelinated axons and causing extensive lesion cavity.

Hypertrophic ligamentum flavum: Thickening of the ligamentum flavum for the aging process causing central canal stenosis and associated to TSCI in a stable spine combined with trauma in hyperextension.

Finite-element analysis: Physical phenomenon simulation using a numerical technique called finite element method (FEM) to reproduce some situations and reduce the number of physical prototypes to optimize study designs.

Dynamic spinal canal encroachment: Invasion of the canal that occurs with movement or by gravity It is well recognized that the dynamic spinal canal encroachment during the trauma is significantly greater than the static canal encroachment seen on post-trauma imaging (Panjabi et al., 1995; Wilcox et al., 2003).

Key facts

Key facts of central cord syndrome (CCS) or spinal cord injury (SCI) in a stable spine.

- Not all the SCIs happen in an unstable spine. In a spine with limited capacity of the vertebral canal, extra physiologically motion can result in SCI.
- Due to aging of population there is a growing number of patients with cervical SCI without instability associated with degenerative changes of the cervical spine.
- Traumatic central cord syndrome (TCCS) is a clinical entity that implies predominant impairment of upper extremities compared to relatively spared lower extremities in the setting of an incomplete SCI.
- TCCS is often found in elderly patients with degenerative cervical spine and no over spinal instability, despite being the most common incomplete SCI it lacks well defined diagnostic criteria.

Key facts of morphology of the fractures and biomechanical factors of SCI.

- Between variables such as low- and high-energy trauma and fracture morphological patterns, are these last ones which explain in a better way the level of energy transferred to the spinal cord.
- Cadaveric and animal models are used to study biomechanics of fractures, finding burst fractures and dislocations as the most common injury patterns, also to understand the biology of spinal cord injury and the effects of other relevant factors as injury mechanism, injury velocity, and residual compression.
- The weight-drop animal injury model was developed in 1911 and has evolved significantly, and it can classify the SCI mechanism, such as contusion, compression, dislocation, distraction, and transection.

Summary points

- Indirect injury to the spinal cord results from the motion (e.g., flexion, hyperextension, axial compression, distraction, dislocation, etc.) between spinal elements during the trauma, causing excessive tension, shear, torsion, compression and/or bending loads on the spinal cord.
- In line with the definition by White and Panjabi, we define traumatic spinal instability to be the loss of the ability of the spine to maintain normal alignment and motion between spinal segments in such a way that a secondary injury to the spinal cord will not occur.
- Wilson et al. showed that cervical dislocation is more frequently associated with severe neurological deficit and high-energy trauma mechanisms, and results in a diminished potential for recovery.
- More often, thoracic TSCI results from high-energy trauma mechanisms. Thorough clinical and radiological evaluation of the thoracic cage should be performed to assess the stability of the spine injury because the great majority of thoracic TSCI will involve an associated disruption of the thoracic cage.
- The velocity of a retropulsed fragment was the most important factor influencing the stresses and strains on the spinal cord, followed by a fracture of the postero-inferior vertebral body wall and sagittal rotation of the retropulsed fragment.
- Although the loss of integrity of PLC is a crucial element for surgeons to determine indication for surgery in thoracolumbar trauma, it remains to be defined whether injury to the PLC is associated with the occurrence and severity of TSCI.

SCI spinal cord injury

Introduction

Anecdotical reports concerning modifications of the perception of the body, space, and action following a spinal cord injury (SCI) are well known to professionals that have experienced with these patients as they can report body misperceptions (e.g., phantom limb or body loss), misrepresentations of space (e.g., body or limbs position, distance lengthening), changes in action representation (e.g., illusionary and phantom limb movement leading to muscular fatigue) (Cole, 2004; Conomy, 1973; Curt, Yengue, Hilti, & Brugger, 2011; Scandola et al., 2017). These sensations, linked to pain, the level of the lesion and the time passed since the lesion onset (Scandola, Aglioti, Avesani, et al., 2017), are symptoms of neuroplastic changes in areas related to the body, space, and action representation.

A spinal cord interruption, especially when this is not developmental but acquired, abruptly changes the brain–body communication. This modification alters the balance between the body sensorial inputs, the signals sent toward it, and the brain activity, leading to abnormalities in cortical and subcortical activity. Consequently, the brain neuroplastically changes itself (Nardone et al., 2013) into brain networks that are involved in body, space, and action representations. Therefore, modifications in these cognitive functions are likely to occur.

This chapter is organized as: a first section reviewing the main literature concerning neuroplastic modifications in SCI individuals, underlying those related to the body, space, or action representations, the following three sections will show the experimental outcomes from studies concerning these representations in SCI individuals, and a fourth section will highlight the experimental results showing the effects of rehabilitative trainings on these representations.

Finally, a concluding section will present the main findings, interpretations, and connections.

The neuroplasticity following SCI and the networks involved in the body, space, and action representations

Neuroplasticity mechanisms have been recently investigated in SCI. Different levels of activation in the sensory and motor cortices have shown, particularly a reduction of activity in areas corresponding to paralyzed limbs (Jurkiewicz, Mikulis, Fehlings, & Verrier, 2010) along with increased activation in areas corresponding to spared body parts (Aguilar et al., 2010; Curt, Bruehlmeier, Leenders, Roelcke, & Dietz, 2002).

Other studies (Henderson, Gustin, Macey, Wrigley, & Siddall, 2011) showed the expansion of the cortical hand area toward the leg area during upper limbs movements. An enlargement of the face representation in the surrounding areas in monkeys after SCI was observed in the primary and nonprimary somatosensory cortices (Tandon, Kambi, Lazar, Mohammed, & Jain, 2009).

Other works found a general reorganization of somatotopic areas (Ghosh et al., 2012; Lundell et al., 2011) and their degeneration over time (Freund et al., 2013).

Diagnosis and Treatment of Spinal Cord Injury. https://doi.org/10.1016/B978-0-12-822498-4.00003-8

All these neuroplastic changes relate to the body, space, and action representations; indeed, all the somatotopic areas are involved in BR (Berlucchi & Aglioti, 2010). Moreover, in BR, the posterior parietal cortex, integrating multisensory inputs and outputs has a fundamental role (Bonda, Petrides, Frey, & Evans, 1995) as this brain area is directly involved in the neuroplasticity following SCI, because of the sensorial modifications.

The understanding of others' actions and space representations rely also on somatosensory cortices. In fact, the fronto-parietal "mirror" network (Rizzolatti, Cattaneo, Fabbri-Destro, & Rozzi, 2014) includes the ventral premotor cortex and the inferior frontal gyrus. Space perception involves the intraparietal sulcus, the lateral occipital complex, and the premotor cortex (Makin, Holmes, & Zohary, 2007; Sereno & Huang, 2006) in the peripersonal space representation, while the extra-personal space perception is linked to an occipito-parietal circuit, a parieto-prefrontal pathway, and a parieto-premotor one (Kravitz, Saleem, Baker, & Mishkin, 2011).

The unbalance between the somatosensory and other sensory feedbacks, causing fundamental changes in the neurological system after SCI, might cause of maladaptive neuroplasticity in these cognitive representations, causing modifications that may be subtle, or evident like phantom sensations (Moore, Stern, Dunbar, Kostyk, & Gehi, & Corkin, 2000) and neuropathic pain (Wrigley et al., 2009).

The body representations

Body ownership is an important aspect of our body representations (BR) and can be defined as the sensation that a bodily part is part of our body. Relevant disturbances can lead to Asomatognosia (Jenkinson, Moro, & Fotopoulou, 2018), namely abnormalities in various facets of body ownership such as the experienced existence, visual self-recognition, and sense of belonging to contralesional body parts.

This facet of BR, investigated by the rubber-hand paradigm, appears to be modified according to neuroplastic cortical modifications. In the commonest version of the rubber-hand illusion (see Fig. 1, Botvinick & Cohen, 1998), participants

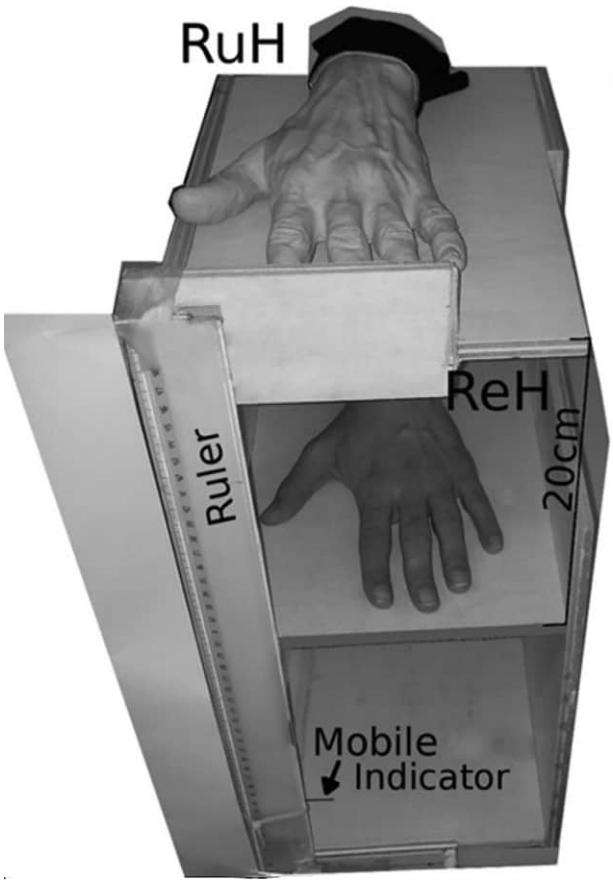

FIG. 1 Rubber hand experimental set-up used in Scandola et al. (2014): Experimental wooden box (RuH, Rubber Hand; ReH, Real Hand), the mobile indicator was always visible to the participant laterally to the box.

observe a rubber-hand, i*n a congruent position with* their own body, synchronously touched with their hand, hidden from sight (Botvinick & Cohen, 1998). An asynchronous rubber-hand/real-hand touch should not elicit a body ownership sensation and, therefore, is used as control condition (Botvinick & Cohen, 1998).

In hand representation-deprived tetraplegics, the ownership sensation toward a rubber hand can be elicited by the synchronous tactile stimulation of the left cheek and the rubber hand (see Fig. 2; Scandola et al., 2014). This is probably caused by the overlapping of the cheek somatic and motor representations over the representation of the hand that are normally contiguously represented (Ramachandran, Stewart, & Rogers-Ramachandran, 1992). A similar result with synchronous visuo-tactile stimulation of the upper back and rubber legs in SCI individuals with complete paraplegia was found (Pozeg et al., 2017). Moreover, the subjective verbal report of the sensation of body ownership toward a body part seems to be captured by the mere vision of the body part, especially when there is a total lack of tactile sensations (lower limbs in people affected by complete paraplegia: Scandola et al., 2020; rubber hand in a patient affected by tetraplegia: Tidoni, Grisoni, Liuzza, & Aglioti, 2014).

A further, implicit paradigm to study body ownership relies on the body-view enhancement effect. This task exploits the effect of visual stimuli appearing on our body that evoke faster reactions than visual stimuli appearing on the same space location, but on a neutral surface (Kao & Goodale, 2009). By a modified version of this paradigm, it was observed that individuals affected by complete paraplegia feel body ownership for the parts of the body that have spared sensory and motor functions, but also the same level of body ownership for their wheelchair, while the lower limbs show no body ownership (Scandola et al., 2019). Interestingly, the same task executed with the SCI participant seated in a different, never used before, wheelchair shows that this redefines their whole BR: there is *no* body ownership toward the new wheelchair, the lower limbs, nor for the part of the body that has spared motor and sensory functions (Scandola, Togni, et al., 2019).

The notion of body schema dates back to the seminal work of Head and Holmes (1911) and can be nowadays defined as the dynamic representation of body parts and their movements, which derives from multiple sensory and motor inputs (e.g., proprioceptive, vestibular, tactile, visual, efference copy). Patients with an impaired body schema are not able to distinguish the position of their arm when their eyes are closed.

A popular experimental paradigm investigating this aspect is the Mental Body Rotation paradigm (Parsons, 1987). According to this, individuals are asked to identify the laterality of a hand or a foot presented on screen at different rotations. The underlying mechanisms of decision imply that participants rotate the bodily stimuli congruent with their body and, therefore, response times (RTs), required to align series of gradually more rotated images to the vertical congruent with the body position, are slower. This leads to a typical RTs pattern, characteristic of a normal body schema representation, called bio-mechanical effect (Parsons, 1987).

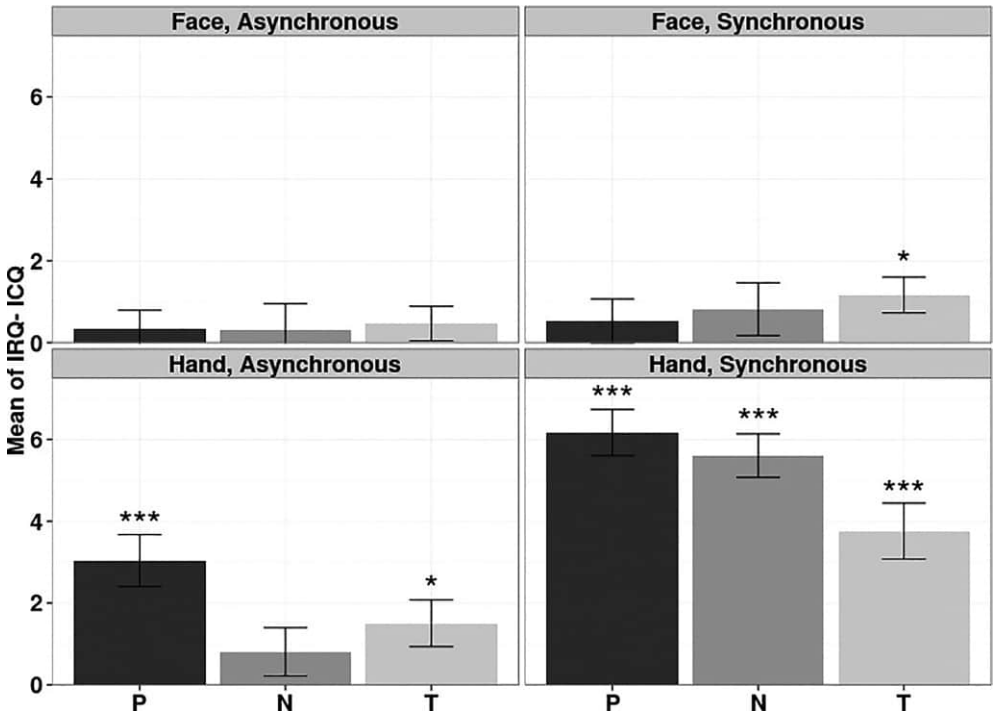

FIG. 2 Results from Scandola et al. (2014): Presence of body ownership in the paraplegics (P), tetraplegics (T), and control healthy (N) groups.

Mental Body Rotation paradigm confirms that complete SCI disrupts the influence of postural changes on the representation of the deafferented body parts (feet, but not hands) and, regardless the posture, whole-BR progressively deteriorates proportionally to SCI completeness (Ionta et al., 2016), as a direct effect of the somato-sensation lack in the affected body-parts in SCI individuals.

Indeed, in SCI participants, the misproprioception of the paralyzed body parts is not uncommon (77% of cases) and it is present in all people affected by complete tetraplegia (Scandola, Aglioti, Avesani, et al., 2017).

Also Disownership-like and Somatoparaphrenia-like sensations (sensations of not owning their own limbs, even attributing them to someone else, as in the latter case) are often reported (48% and 46%, respectively), altogether to illusory motion of paralyzed body parts (51%).

In all these cases, these bodily illusions are connected to the time since the lesion onset, the level of injury, and the presence of pain (Scandola, Aglioti, Avesani, et al., 2017).

Interestingly, these bodily illusions are less evident in presence of neuropathic and visceral pain. This apparently counterintuitive result addresses toward the fact that, in a deafferented/deefferented body, a pain sensation coming from the impaired body part is used by our cognitive system as a surrogate BR.

The action representation

The representation of actions is fundamental in our everyday life. It allows us to plan our gestures, interact with the environment and other people. The representation of actions is based on the fronto-parietal "mirror" network (Aglioti, Cesari, Romani, & Urgesi, 2008; Avenanti, Candidi, & Urgesi, 2013; Calvo-Merino, Glaser, Grèzes, Passingham, & Haggard, 2004; Panasiti, Pavone, & Aglioti, 2016).

In matching-to-sample experiments, participants are presented with a single stimulus called the sample and then with two choice stimuli called the comparisons. The participants have to select the comparison that matches the sample. A version of this paradigm that used images of bodies that could be different for body action or body form, for the whole body, in its upper part, or in the lower part, was applied to a sample of complete paraplegics and healthy controls (Pernigo et al., 2012). Results showed that complete paraplegics participants had slower reaction times and greater errors incidence, in body images that were different for the lower part of the body, than the control group of healthy participants.

These results were confirmed and widened by using a Temporal Occlusion Paradigm (Scandola, Aglioti, et al., 2019) where participants observed two sets of videos depicting an actor who attempted to climb onto a platform using a wheelchair or rollerblades. Each video could end in three different ways: (a) successfully (the actor went up the step), (b) failing (the actor stopped before the step without going up), or (c) falling (the actor fell without going up). Each video was cut in five different durations at 600, 1200, 1800, 2400, and 3000 ms. In the shortest (600 ms) clip, only preparatory body movements were shown, while in the longest (3000 ms), the complete action (see Fig. 3).

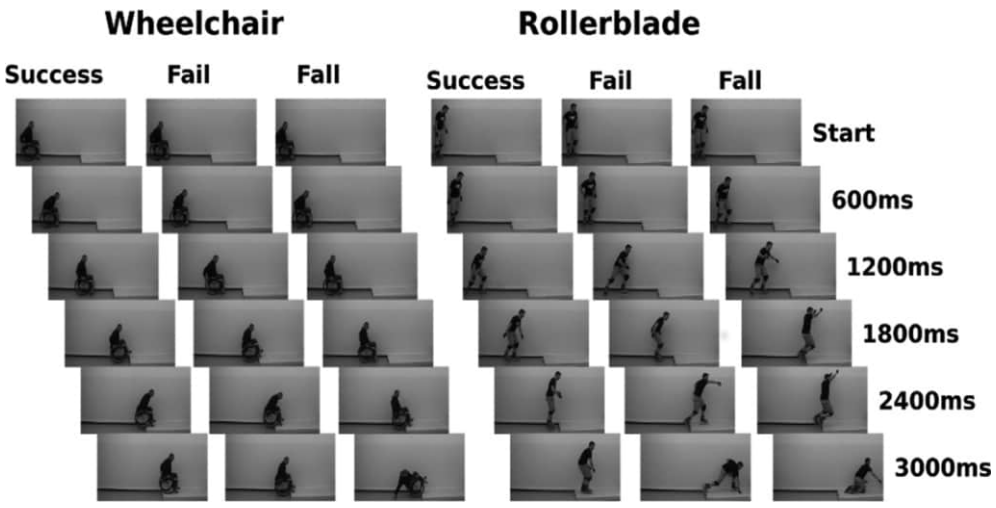

FIG. 3 Stimuli used in Scandola, Aglioti, et al. (2019): Wheelchair and rollerblade videos at different durations (Start, 600, 1200, 1800, 2400, 3000 ms) for the three endings.

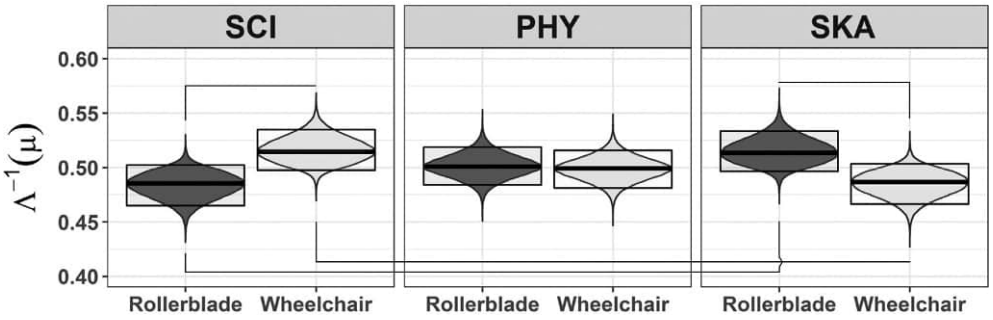

FIG. 4 Results from (Scandola, Aglioti, et al., 2019): a Temporal Occlusion Paradigm in anticipating the ending of wheelchair or rollerblade videos in *SCI* = spinal cord injured people; *PHY* = physiotherapists; *SKA* = skaters. Higher values mean better performance.

Participants had to report the outcome of the video choosing among success, fail, or fall. Participants were divided in three groups: the complete paraplegics group, the expert skaters group, and a group composed by physiotherapists that had at least 1 year of experience in a spinal-unit, but no experience in rollerblades or other skating tools.

Results from this study showed that complete paraplegics participants had a worse performance in rollerblades videos compared to the Skaters group, but also compared to the Physiotherapists group, inexperienced in skating (see Fig. 4), suggesting that abnormalities in the mirror system for the lower limbs affect the recognition of lower limbs' actions in a subtle, but still worsening way compared to a group that had no direct experience in the action.

A further indication regarding modifications in the action representation system derives from the tendon-vibration illusion, able to induce illusory perception of movement (Tidoni et al., 2015). The application of this illusion to individuals affected by SCI induced movement illusions that were qualitatively different from the healthy control sample (e.g., as if the arm wanted to extend itself, or a sensation of pushing against something) that may reflect different reorganization processes following SCI (Fusco, Tidoni, Barone, Pilati, & Aglioti, 2016).

The modifications in the action representations could also affect the learning of new motor sequences. In fact, according to Bloch and colleagues (Bloch, Tamir, Vakil, & Zeilig, 2016), it exists a specific deficit in implicit learning of motor sequences in SCI people, and it may be extended even in the motor learning abilities consequently a SCI lesion.

However, complete SCI participants demonstrated a better performance in forecasting the outcome of wheelchair action in a Temporal Occlusion Paradigm than Physiotherapists working in a Spinal Cord Unit and a group of expert skaters (Scandola, Aglioti, et al., 2019). Interestingly, experimental results confirmed that agonistic wheelchair-basket players showed a better performance with images changing only in the upper-part of the body than control healthy agonistic basketball players (Pernigo et al., 2012); moreover, a greater EEG observational contingent negative variation waveform, considered a marker of action effect prediction, during the evaluation of free throws videos, than control participants (Özkan, Pezzetta, Moreau, Abreu, & Aglioti, 2019). Finally, Bloch, Shaham, Vakil, Ashkenazi, and Zeilig (2020) with a different experimental paradigm could not replicate the impairment of implicit motor learning previously reported. Therefore, the motor learning impairment in SCI is probably not present, or it is very specific for some motor nonecological tasks.

Another aspect of action representation is the motor imagery. This can be defined as the act to internally represent an action, without its execution (Jackson, Lafleur, Malouin, Richards, & Doyon, 2001). Nonetheless, motor imagery involves the activation of brain structures involved in action performance, such as premotor areas and the left intraparietal sulcus, even *if* at a minor level than actual action performance (Bonda et al., 1995; Decety, 1996; Nikulin, Hohlefeld, Jacobs, & Curio, 2008).

While in some studies, motor imagery seems to be spared after SCI (Decety & Boisson, 1990; Hotz-Boendermaker et al., 2008), altered cortical activations were found (Alkadhi et al., 2005; Cramer, Orr, Cohen, & Lacourse, 2007).

In particular, during motor imagery tasks, the primary and nonprimary motor cortices, and subcortical structures are more activated in individuals affected by SCI than control subjects (Alkadhi et al., 2005), even if the imagery does not involve paralyzed limbs (Alkadhi et al., 2005). Similarly, the minor activation of the primary motor cortex shown by healthy individuals during imagined movements compared to real movements, it is not present after SCI (Di Rienzo et al., 2014), suggesting that after SCI, the motor cortices are activated in the same way during motor imagery or real movements.

Experimental reports suggest that these effects lead to a different motor imagery strategy after SCI for subjective responses (Fiori et al., 2014). In fact, from behavioral investigations, motor imagery after SCI appears to be somatotopographically organized, with higher ability for the spared body parts, and it is impaired in presence of neuropathic pain (Scandola, Aglioti, Pozeg, et al., 2017).

The space representation

The study of the space representation, since the seminal works by Rizzolatti and colleagues (Rizzolatti, Scandolara, Matelli, & Gentilucci, 1981) was divided in extrapersonal and peripersonal space, two spaces that can be broadly defined respectively as the space outside and within the reach of our limbs.

PPS representation is somatotopically organized: different extensions were found for the hands, trunk, head, and lower limbs (Schicke, Bauer, & Röder, 2009; Serino et al., 2015; Stone, Kandula, Keizer, & Dijkerman, 2017). It is modulated by several aspects of our everyday life, such as action (Brozzoli, Cardinali, Pavani, & Farnè, 2010), danger and fear (Sambo, Liang, Cruccu, & Iannetti, 2011), and stimuli valence (Spaccasassi, Romano, & Maravita, 2019).

PPS is somatotopically modulated by the presence of SCI, but this representation can be recovered with an action-based training. While the upper limbs PPS representation in paraplegics is preserved (Scandola, Aglioti, Bonente, Avesani, & Moro, 2016; Scandola et al., 2020; Sedda et al., 2018), the PPS around the lower limbs is shrunk (Scandola et al., 2016, 2020). However, applying passive mobilization on lower limbs can recover their PPS representation (Scandola et al., 2016).

The representation of the extrapersonal space is also modulated by action and metabolic energy. According to the Economy of Action principle (Proffitt, 2006), the perceptual representation of the space around us is modulated by our metabolic energy, in order to spare energetic resources, mostly when they are lacking. Therefore, when we are in a low physiological condition, or in a physically demanding situation, distances to be (implicitly) walked are perceived longer, and slopes are perceived stepper (Proffitt, 2006).

Indeed, experimental results showed that in estimating the slope of a hill or distance, people tend to overestimate when wearing a heavy backpack (Bhalla & Proffitt, 1999). These effects may be elicited by poor physical health, fatigue (Bhalla & Proffitt, 1999), while the opposite effect is appreciable after the assumption of energy beverages (Schnall, Zadra, & Proffitt, 2010). Thus, the characteristics of the perceptual representation of the extrapersonal space that are potentially linked to a bodily demanding action will be overestimated to prevent the action execution. Therefore, perceptual errors are natural, and they increase as the required effort increases.

In a virtual-reality task, participants affected by complete paraplegia saw a flag depicted on an ascending wheelchair ramp that could have different degrees of slant. Participants had to estimate the distance from the flag on their own wheelchair, or on a wheelchair never used before.

Distance estimation errors were modulated by the degrees of slant of the ramp only when they were seated on their own wheelchair, while on the other wheelchair, the estimation errors were constant (Scandola, Togni, et al., 2019), suggesting that only when they are on their wheelchair they are able to implicitly represent the action of reaching the flag, allowing a representation of space that follows the Economy of Action principle (Proffitt, 2006).

The effects of rehabilitation on the body, action, and space representations

Physiotherapy interventions can significantly affect, not only from a rehabilitative point of view, but they can likewise be beneficial for the body, action, and space representations.

In particular, the effects of physiotherapy training on body schema representation were studied on a sample of 21 individuals affected by SCI. Before starting the training, and at the end of it, participants underwent a Mental Body Rotation paradigm (Parsons, 1987), with stimuli depicting a left or right hand, foot, or a body (Scandola, Dodoni, et al., 2019). Before the training, SCI participants and a group of healthy participants showed the same pattern for hands and bodies stimuli, while with feet stimuli, only the healthy group showed the bio-mechanical effect. Interestingly, the level of completeness of the lesion covaried with RTs with feet stimuli: slower RTs were associated with more complete lesions, suggesting a greater difficulty in processing stimuli concerning paralyzed body parts.

After the physiotherapy intervention, the bio-mechanical effect appeared also with feet stimuli in the SCI group, showing that a rehabilitative intervention has also effects on the body schema representation (Scandola, Dodoni, et al., 2019).

Another fascinating study, added to the normal physiotherapy rehabilitation a motor imagery training to tetraplegic patients and a control group. Results from magneto-encephalography showed that before the training in the SCI group, there was a compensatory recruitment, with a higher activation of more areas during motor imagery tasks than the control group. Immediately after the training, and after 2 additional months, the SCI group showed a recruitment similar to the control group (Di Rienzo, Guillot, Daligault, et al., 2014).

The impact of rehabilitative training, in particular when they involve the mobilization of paralyzed limbs, is evident also in the PPS representation. In 2016, a study from our group noticed that PPS in complete paraplegics individuals is shrunk around the feet, though a passive mobilization lasting 15 min can recover it (Scandola et al., 2016).

FIG. 5 Pictures from the videos used in Scandola et al. (2020). (A) Video in first-person perspective of passive mobilization. (B) Video in first-person perspective of no mobilization.

Importantly, this recovery is not present when the passive-mobilization is only visual (e.g., the lower limbs are not actually moved, but participants observe a virtual-reality video showing their legs being moved, see Fig. 5).

Results clearly showed that in complete paraplegic participants, the real motor component of the passive mobilization is needed for PPS representation recovery (Scandola et al., 2020). Connected with this latter finding, complete paraplegic individuals could detect when their legs were moved, even if they could not see them, notwithstanding their lack of proprioception (see Fig. 6), better than random guesses (Scandola et al., 2020). Moreover, PPS recovery was modulated by interoception sensitivity in participants affected by incomplete paraplegia: greater interoceptive sensitivity leads to a greater lower-limbs PPS recovery (Scandola et al., 2020).

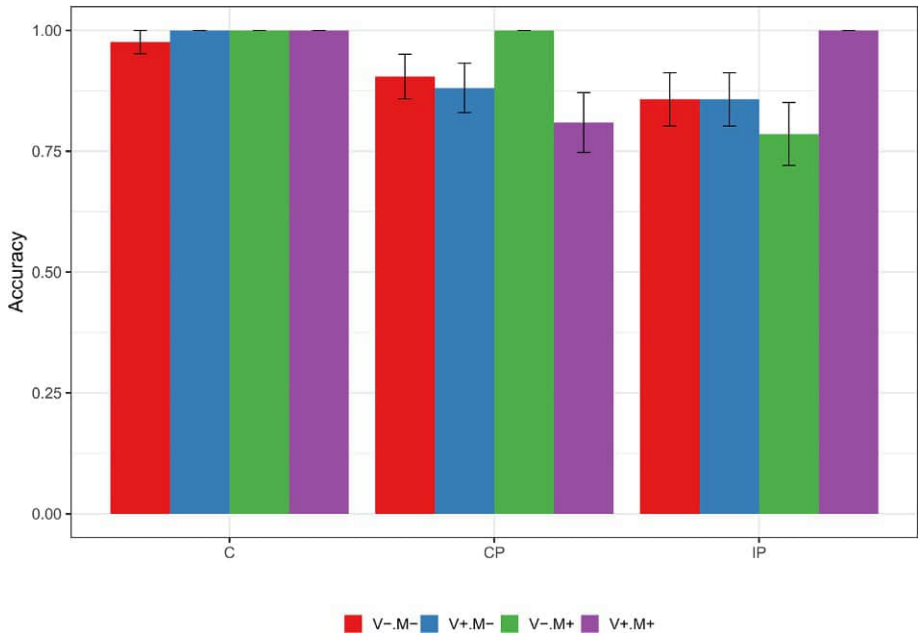

FIG. 6 Accuracies of the detection of motion of the lower legs during the 4 stimulations: V+ = video showing passive visual mobilization, *V-* = video showing no visual mobilization; *M+* = real mobilization; *M−* = no real mobilization. *C* = control group; *CP* = complete paraplegics group; *IP* = incomplete paraplegics group. *Adapted from Scandola, M., Aglioti, S. M., Lazzeri, G., Avesani, R., Ionta, S., & Moro, V. (2020). Visuo-motor and interoceptive influences on peripersonal space representation following spinal cord injury.* Scientific Reports, 10*(1), 1–16. https://doi.org/10.1038/s41598-020-62080-1*.

Conclusions

The neuroplastic changes following SCI involve modifications of the body, space, and action representations (see Table 1 for a summary). Modifications in such representations are often considered as a cause of maladaptive plasticity that is related to phantom limb and neuropathic pain (Moore et al., 2000; Wrigley et al., 2009).

Modifications in the body, action, and space representations seem to follow the somato-topography rule: but only representations involving paralyzed limbs (Scandola, Aglioti, et al., 2019; Scandola et al., 2016, 2020, 2014).

Importantly, the possibility of new motor learnings and the action-dependent recovery of the representation of the space suggest top-down and bottom-up influences on above representations (Bloch et al., 2020; Pernigo et al., 2012; Scandola et al., 2016, 2020).

Also, BRs are impacted by bottom-up and top-down influences. For example, neuropathic and visceral pain sensations coming from the part of the body that is deafferented/deefferented seem to protect from body illusions, working as surrogate of normal BR (Scandola, Aglioti, Avesani, et al., 2017). Moreover, the wheelchair does not seem only the most iconic symbol representing the condition of individuals affected by SCI, but also a tool that is able to shape and define their BRs (Scandola, Togni, et al., 2019), and the extrapersonal space representation (Scandola, Togni, et al., 2019).

These results indicate that the body, space, and action representations rehabilitation is possible, and it might have beneficial neuroplastic effects on maladaptive plastic mechanisms (Di Rienzo, Guillot, Mateo, et al., 2014; Scandola et al., 2016, 2020). A further step might be a training focused on these representations, that side by side to a conventional physiotherapy training could improve rehabilitative outcomes.

Applications to other areas of neuroscience

In this chapter, we have reviewed the neuroplastic modifications in the body, space, and action representations following complete or incomplete spinal cord injuries.

TABLE 1 Summary of the main findings concerning body, action, and space representations in spinal cord injuries.

Domain	Subdomain	Finding	References
Body representation	*Explicit body ownership*	Visuo-tactile stimulations induce body ownership over a rubber body part, also when the tactile stimulus is administered to a body part that is different from the rubber one. This may be caused by the neuroplasticity involving the motor and somato-sensory cortexes, or by the mere vision of the rubber body part	Scandola et al. (2014), Pozeg et al. (2017), Tidoni et al. (2014)
	Implicit body ownership	Body Ownership is somatotopically modulated over the body, reduced over the paralyzed and anesthetized body parts, and it is extended to the wheelchair. The use of a new wheelchair can impair Body Ownership over the whole body	Scandola, Togni, et al. (2019)
	Body schema	Complete SCI impairs body schema on the representation of the deafferented body parts (feet, but not hands) and, regardless the posture, whole-BR progressively deteriorates proportionally to SCI completeness, as a direct effect of the somato-sensation lack in the affected body-parts in SCI individuals Body Schema can be recovered after physiotherapeutic interventions	Ionta et al. (2016), Scandola, Dodoni, et al. (2019)
	Body illusions	Various body representation illusions are reported for SCI individuals: • Misproprioception of the paralyzed body: 77% • Disownership-like sensation: 48% • Somatoparaphrenia-like sensations: 46% • Illusory motion of paralyzed body parts: 51% These are reduced by the presence of visceral or neuropathic pain: pain sensations coming from the impaired body part are used by our cognitive system as a surrogate body representations in absence of other somatic sensations	Scandola, Aglioti, Avesani, et al. (2017)

TABLE 1 Summary of the main findings concerning body, action, and space representations in spinal cord injuries—cont'd

Domain	Subdomain	Finding	References
Action representation	*Action discrimination*	Complete paraplegics participants have slower reaction times and greater errors incidence, in body images that were different for the lower part of the body, than the control group of healthy participants Agonistic wheelchair-basket players have a better performance with images changing only in the upper-part of the body than control healthy agonistic basketball players A greater EEG observational contingent negative variation waveform (marker of action effect prediction) is observed during the evaluation of free throws videos, than control participants	Pernigo et al. (2012), Özkan et al. (2019)
	Action anticipation	Complete paraplegics participants have worse performances in guessing the final outcome of rollerblades videos compared to the Skaters group, but also compared to the Physiotherapists group, inexperienced in skating, suggesting that abnormalities in the mirror system for the lower limbs affects the recognition of lower limbs' actions in a subtle, but still worsening way compared to a group that had no direct experience in the action	Scandola, Aglioti, et al. (2019)
	Tendon vibration illusion	Movement illusions are qualitatively different from the healthy control sample (e.g., as if the arm wanted to extend itself, or a sensation of pushing against something), reflecting different reorganization processes following SCI	Fusco et al. (2016)
	Implicit learning	In a study (Bloch et al., 2016) SCI participants showed a specific deficit in implicit learning of motor sequences However, this result was not confirmed by the result of another study of the same group (Bloch et al., 2020)	Bloch et al. (2016), Bloch et al. (2020)
	Motor imagery	During motor imagery tasks, the primary and non-primary motor cortices, and subcortical structures are more activated in individuals affected by SCI than control subjects. SCI participants use a different strategy for motor imagery based on memory instead of on body representations, and it is impaired by neuropathic pain sensations. Adding motor imagery tasks to the normal physiotherapy rehabilitation for 2 months leads to a normalization in the cortical activation of SCI participants	Alkadhi et al. (2005), Di Rienzo, Guillot, Daligault, et al. (2014), Fiori et al. (2014), Scandola, Aglioti, Pozeg, et al. (2017)
Space representation	*Peripersonal space*	PPS in SCI is somatotopically impaired: the representation of upper-lesion body parts is spared, while the representation of lower-lesion body parts is shrunk. The application of passive mobilization on lower limbs can induce a short-term recovery. This passive mobilization must involve actual mobilization: the simple observation of movement is not enough	Scandola et al. (2016), Scandola et al. (2020), Sedda et al. (2018)
	Extrapersonal space	Distance estimation errors are modulated by the embodiment of the wheelchair in use. If the tool used to move in the surrounding space is embodied (i.e., they are using their own wheelchair), the distance estimation errors are modified by the difficulty in reaching that distance, as in healthy subjects that are able to internally represent the action. If the wheelchair is not embodied (i.e., they are using a never-used-before wheelchair), the action representation becomes impossible and purely visual strategies are then used in order to estimate space	Scandola, Togni, et al. (2019)

The neuroscientists, or the neurologists interested in the modifications of these representations, and their interconnections with rehabilitative and theoretical or neurophysiological aspects, will be interested in these studies.

The study of the body, space, and action representations has often used studies on neurological patients (Buxbaum, Giovannetti, & Libon, 2000; Candia, Wienbruch, Elbert, Rockstroh, & Ray, 2003; Canzoneri, Marzolla, Amoresano, Verni, & Serino, 2013; Sirigu, Grafman, Bressler, & Sunderland, 1991; Soman, Steeves, & Lang, 2009; Tinazzi, Fiorio, Bertolasi, & Aglioti, 2004). However, SCI participants may represent an ideal model to explore to what extend sensorimotor deficits alter cognitive functions. In fact, in this population, all the postlesional changes in cognitive functions do not depend on brain damage or modifications in their body form but are exclusively related to the loss of sensory–motor afferences from as well as efferences to the disconnected body parts.

Furthermore, for the neuroscientists interested in rehabilitation of cognitive and motor skills, the above-reviewed studies here reviewed show trainings that are designed to counter maladaptive plasticity and neuropathic pain, and improve adaptive neuroplasticity (Mateo et al., 2015; Scandola et al., 2020; Scandola, Dodoni, et al., 2019).

Mini-dictionary of terms

Neuroplasticity: the natural modifications of the brain areas, through growth and reorganization.
Body ownership: our sensation of owning a part of our body.
Rubber hand illusion: an experimental paradigm used to investigate body ownership, where a sensation of body ownership is elicited toward a rubber hand by means of synchronous visuo-tactile stimulation of the rubber hand and the participant's real hand.
Body-view enhancement effect: visual stimuli appearing on our body evoke faster reactions than visual stimuli appearing on the same space location, but on a neutral surface.
Body schema: the representation of the body parts position, in relation to the rest of the body.
Mental Body Rotation Paradigm: In this experimental paradigm, individuals are asked to identify the laterality of a hand or a foot presented on screen at different rotations. The underlying mechanisms of decision imply that participants rotate the body stimuli in a canonical position congruent with their body and therefore, response times (RTs) required to align series of gradually more rotated images to the vertical, congruent with the body position, are slower. This leads to a typical RTs pattern, characteristic of a normal body schema representation, called bio-mechanical effect.
Motor imagery: the act to internally represent an action, without its execution. It has to do with the activation of the same brain areas involved in the execution of the action, even though at a minor level.
Peripersonal space: the space within the reach of our limbs.
Extrapersonal space: the space outside the reach of our limbs.
Temporal Occlusion Paradigm: in this experimental paradigm, participants are asked to predict the outcome of an action seen in a video that has been occluded at a specific time-point, before the end of the action.

Key facts of neuroplasticity following spinal cord injury

1. Brain modifications after spinal cord lesion starts within minutes from the lesion, as seen in animal models
2. The neuroplasticity leads to reduction of activity in the areas corresponding to paralyzed limbs
3. In the brain areas connected to the upper-lesion body parts the activity is increased
4. This neuroplasticity can cause phantom limb sensations
5. Maladaptive neuroplasticity can cause neuropathic pain
6. It is also the cause of modifications in body, action, and space representations

Summary points

1. The neuroplastic modifications following a spinal cord injury change the body, action, and space representations with maladaptive consequences
2. The modifications in the body representations do not only involve the parts of the body below the lesion, but also the whole body
3. In individuals with chronic spinal cord injuries, that use the wheelchair for a long time, the wheelchair is part of their body representation and can define it
4. The action representation is impaired for the parts of the body below the lesion
5. The peripersonal space representation is somato-topographically modified: it only involves the parts of the body that are below the lesion
6. The body, action, and space representations can be rehabilitated using motor imagery and physiotherapeutic training.

Chapter 4

Methods for treating pain and painful syndromes in spinal cord injury: Medications, therapies, interventions, and neuromodulation

James J. Bresnahan, James C. Pendleton, Benjamin R. Scoblionko, Patricia Orme, and Philip J. Koehler, III
Department of Rehabilitation Medicine, Thomas Jefferson University Hospital, Philadelphia, PA, United States

List of abbreviations

AB	able-bodied
CNS	central nervous system
DRGS	dorsal root ganglion stimulation
IL	interleukin
PAG	periaqueductal gray
PNS	peripheral nerve stimulation
PT	physical therapy
RVM	rostral ventromedial medulla
SNRI	serotonin-norepinephrine reuptake inhibitor
SCI	spinal cord injury
SCS	spinal cord stimulation
tDCS	transcranial direct current stimulation
TENS	transcutaneous electrical nerve stimulation

Introduction

Pain frequently limits activities, decreases quality of life, and leads to significant psychological impairment independent of other functional deficits after SCI (Craig et al., 2015; Elliott & Frank, 1996; Finnerup et al., 2016). In general, SCI pain is not well understood from the cellular, molecular, and even spinal cord pathway levels (Siddall, Taylor, & Cousins, 1997).

Sixty-five percent to eighty percent of individuals with SCI live with chronic pain, and nearly one third rate this pain as severe (Cardenas, Bryce, Shem, Richards, & Elhefni, 2004; Finnerup et al., 2016; Siddall, Mcclelland, Rutkowski, & Cousins, 2003). About half of all individuals with SCI suffer from pain so severe that it interferes with function and rehabilitation independent of deficits related to their SCI (Siddall & Loeser, 2001). It is generally believed that level of injury does not have an influence on the degree of post-SCI chronic pain. Penetrating injuries may be more likely to result in chronic pain (Richards, Stover, & Jaworski, 1990), and there is some evidence that incomplete lesions lead to more chronic pain than complete lesions (Beric, Dimitrijevic, & Lindblom, 1988; Davidoff, Roth, Guarracini, Sliwa, & Yarkony, 1987).

Pain after SCI can generally be divided into nociceptive, visceral, at-level neuropathic, and below-level neuropathic (Siddall et al., 1997). It is theorized that SCI pain may be fairly unique and related to relative serotonin, norepinephrine, and dopamine deficits due to loss of supraspinal inhibition (Boadas-Vaello et al., 2016; Bourne, Machado, & Nagel, 2014; Heinricher, Tavares, Leith, & Lumb, 2009). Additionally, there is a well-described inflammatory milieu that occurs after SCI and may contribute to an additional inflammatory basis of pain (Chambel, Tavares, & Cruz, 2020). Furthermore, post-SCI changes are noted in synaptic dendrites in individuals who experience significant pain, suggesting a dynamic neuroplastic component to pain (Benson, Reimer, & Tan, 2020). It is likely the unique combination central nervous system (CNS)

Diagnosis and Treatment of Spinal Cord Injury. https://doi.org/10.1016/B978-0-12-822498-4.00004-X

TABLE 1 Classification of spinal cord injury-related pain.

Classification	Definition
Nociceptive somatic pain	Pain from skin, subcutaneous tissues, bones, joints, connective tissue, muscle, and tendons. Often occurs from overuse, age-related breakdown, or acute injury
Nociceptive visceral pain	Pain from organs and supporting structures. Often occurs with internal injury or infection
At-level neuropathic pain	Pain within 2 levels of the segment of the spinal cord that is injured. Often central or peripheral (radicular) pain that has typical neuropathic qualities
Below-level neuropathic pain	Pain below the level of the injured spinal cord segment related to disruption of the typical neural connections

Original table: These are the four generally agreed-upon classifications of pain as it related to the spinal cord-injured population.

TABLE 2 Characteristics of different pain types.

	Nociceptive pain		
	Somatic pain	**Visceral pain**	**Neuropathic pain**
Pain origin	Skin, subcutaneous tissues, mucous membrane, joints, connective tissue, muscle, and bone	Organs, organ capsule or covering, connecting and supporting structures	Central or peripheral nerves
Location	Localized	Generalized or diffuse	Radiating or specific
Quality	Pinprick, stabbing, sharp, sore, aching	Cramping, throbbing, squeezing, pressure, or sharp	Burning, "pins and needles," tingling, electrical, or lancinating
Mechanism of pain	A-delta fiber activity Located in the periphery	C Fiber activity Involving deeper innervation	Nondermatomal (central), or dermatomal (periphery)
Clinical examples	• Sickle cell crisis • Superficial burns and lacerations • Stomatitis • Intramuscular injections • Spasticity-mediated pain • Bone metastases	• Colic spasm • Appendicitis • Kidney stone • Chronic pancreatitis • IBS • Angina • Menstrual cramps	• Trigeminal neuralgia • Avulsion neuralgia • Posttraumatic neuralgia • Radiculopathy • Peripheral neuropathy • Phantom limb • Herpetic neuralgia

Original table: Differentiating pain generators is important in determining a treatment algorithm. These are the general characteristics of different types of pain.

changes after SCI creates a "pro-pain" state, and not surprisingly, SCI pain is often refractory to medical treatments (Siddall & Loeser, 2001; Widerström-Noga, 2017b).

The treatment of SCI-related pain often comes down to using a multimodal approach with medications, physical interventions, treatment of underlying conditions like spasticity, treatment of acquired overuse syndromes, and potentially the use of neuromodulation interventions. The typical categories of SCI-related pain can be reviewed in Tables 1 and 2.

Application to other areas of neuroscience

There is a growing emphasis on the connection between physical experiences and psychologic interpretation that goes beyond pain management. One particular area of interest has been the neural pathway between the amygdala, periaqueductal gray matter, and rostral ventromedial medulla (RVM). The amygdala stores emotional experiences. It is connected to the periaqueductal gray matter, which contains a high concentration of opioid, cannabinoid, and endorphin receptors (Basbaum & Fields, 1978). The RVM is not involved in generating an initial pain response but does help regulate the maintenance of neuropathic pain (Vera-Portocarrero et al., 2006). The ventral posteromedial nucleus plays a major role in central

sensitization, a condition of the nervous system that is associated with development and maintenance of chronic pain that is caused by increased excitability of cell membranes, synaptic efficiency, and reduced inhibition of nociceptive pathways (Latremoliere & Woolf, 2009). The plasticity of neurons that undergo central sensitization has been the target of newer therapies, though significant mechanistic gaps in our understanding remain (Latremoliere & Woolf, 2009).

These pathways significantly influence pain processing, decision-making, avoidant behavior, and personality expression (Yin et al., 2020) and are thought to modulate opioid-induced analgesia (Samineni et al., 2017). Additionally, recent studies showed modulating this pathway impacts the extent of depression-associated pain in mice under chronic stress (Yin et al., 2020). Physical activity, such as Tai Chi and cycling, has been shown to modulate this opioid pathway, thereby reducing overall pain levels and reducing levels of circulating inflammatory markers (Liu et al., 2019). This concept is fundamental to the use of physical activity to combat pain in patients with depression.

Main narrative text

Physical therapy and exercise

In the AB population, the clinical treatment of pain generally progresses from noninterventional PT-based treatment to more aggressive interventional treatments such as injections and ultimately surgery if there continues to be minimal to no improvement and depending on the pain generator (Patrick, Emanski, & Knaub, 2014; Will, Bury, & Miller, 2018). There are important similarities and differences in treating pain after SCI compared to the AB population. The most common subset of pain in the SCI population is neuropathic pain, either at or below the level of injury (E. Widerström-Noga, 2017a) and generally is not as responsive to PT (Akyuz & Kenis, 2014). However, many individuals have concomitant nociceptive pain (Widerström-Noga, 2017a) that may be more receptive to traditional PT interventions.

Eighty percent of those with SCI pain found PT and exercise helpful to a large extent, second only to cannabis and alcohol in terms of treatment effect (Heutink, Post, Wollaars, & Van Asbeck, 2011). Other studies in the United States (Widerström-Noga & Turk, 2003) noted half of respondents who participated in PT reported "considerable" pain reduction and a study from Sweden (Norrbrink Budh & Lundeberg, 2004) noted very high satisfaction rates despite overall low levels of PT utilization. Telehealth PT using high-dose scapular stabilizing and rotator cuff strengthening program in SCI individuals with signs of impingement syndrome was effective in reducing shoulder pain by more than 50% after 24 weeks (Van Straaten, Cloud, Morrow, Ludewig, & Zhao, 2014).

Exercise has been used as an augmentative strategy for many chronic conditions including osteoarthritis, peripheral vascular disease, low back pain, and fibromyalgia (Buckelew et al., 1998; Ettinger, 1997; Hayden et al., 2019; Lane, Ellis, Watson, & Leng, 2014) and there is a linear relationship between frequency, duration, and intensity of exercise and chronic pain (Landmark, Romundstad, Borchgrevink, Kaasa, & Dale, 2011). There are few high-quality studies assessing exercise and pain in the SCI population. Norrbrink, Lindberg, Wahman, and Bjerkefors (2012) noted significant improvement in pain scales and number of days per week with pain in nociceptive and neuropathic pain levels after training on a double-poling ergometer three times per week for 10 weeks at 70%–100% peak heart rate during intervals.

Recently, due to increased consensus on the benefits of exercise after SCI, an SCI exercise guideline was released (Ginis et al., 2018). The PAG, which has high concentrations of opioid and cannabinoid receptors sends projections to the RVM and both areas are activated by aerobic exercise (Chen et al., 2018; Sluka, O'Donnell, Danielson, & Rasmussen, 2013; Stagg et al., 2011). Additionally, there is an antiinflammatory cascade involving downregulation of pro-inflammatory Interleukin (IL)-1B and Tumor necrosis factor-alpha and upregulation of antiinflammatory IL-6 and IL-10 (Chen, Li, Chen, Li, & Hung, 2012; Jankord & Jemiolo, 2004). Some of the potential improvement in pain as it relates to exercise may be a partial function of improved psychological well-being (Latimer, Martin Ginis, Hicks, & McCartney, 2004).

Medications

Medications targeting neuropathic pain after SCI are the best studied. Pregabalin (Lyrica) and gabapentin (Neurontin) are antiepileptics and considered first-line medications in the treatment of neuropathic pain in patients with SCI injury (Loh et al., 2016). In 2012, pregabalin (Lyrica) became the first and remains the only Federal Drug Administration approved medication for neuropathic pain in patients with SCI in the United States. Its approval was based on two double blind placebo controlled randomized trials (Cardenas et al., 2013; Siddall et al., 2006). In the study by Siddall et al. (2006), 70 patients showed improvement in pain and sleep when compared to the control arm of 67 patients. Cardenas et al. (2013) studied 220 patients and exhibited improvement in pain 1 week into treatment. Mehta, McIntyre, Janzen, Loh,

and Teasell (2016) published an updated systematic review from their 2010 publication (Teasell et al., 2010) and cited 13, level-1 randomized controlled trials supporting both the anticonvulsants pregabalin and gabapentin.

Antidepressants are also utilized in treating neuropathic pain in SCI. Like pregabalin (Lyrica) and gabapentin (Neurontin), the tricyclic antidepressants amitriptyline (Elavil), nortriptyline (Pamelor), imipramine (Tofranil), and desipramine (Norpramin) are first-line medications. These medications have only demonstrated efficacy in patients with concomitant depression (Mehta et al., 2016). More recently venlafaxine revealed similar effects to amitriptyline in subjects with pain and depression (Richards et al., 2015). Other antidepressants, such as duloxetine, have not proven to be effective in patients with pain related to SCI (Vranken et al., 2011). Taken together, the serotonin-norepinephrine reuptake inhibitors (SNRIs) duloxetine (Cymbalta) and venlafaxine (Effexor) are considered second-line medications.

Despite common use in practice, opioids have inferior efficacy than previously mentioned medications. Tramadol, a synthetic opioid with SNRI properties, has some efficacy and is a third-line medication (Loh et al., 2016; Norrbrink & Lundeberg, 2009). As a sole agent, tramadol should be employed before other opioids such as oxycodone. Oxycodone is considered a fourth-line medication and has only level 4 evidence supporting its use (Loh et al., 2016; Mehta et al., 2016).

The effects of cannabinoids are mediated via the CB_1 and CB_2 G-protein receptors, where CB_1 is widely expressed in the CNS (Zajicek & Apostu, 2011). Interestingly, CB_1 is upregulated following SCI (Knerlich-Lukoschus et al., 2011). The analgesic properties of cannabinoids are mediated through the PAG (Heinricher et al., 2009; Raichlen, Foster, Gerdeman, Seillier, & Giuffrida, 2012). Indirect effects on opiate, serotonin, NMDA, and GABA receptors link endocannabinoids to other pain-related pathways (Hill, 2015; Raichlen et al., 2012; Woolridge et al., 2005). A metaanalysis of five randomized control trials suggests that inhaled cannabis may provide short-term relief for about 20% of patients with neuropathic pain (Andreae et al., 2015). Future studies are needed to assess long-term effects of cannabinoids on neuropathic pain, specifically as it relates to SCI, as well as the optimal route of administration (Inglet et al., 2020). The mechanism of action for medications typically used for the treatment of SCI-related pain can be reviewed in Table 3.

TABLE 3 Medication management of pain in spinal cord injury.

Class of medication	Targeted category of pain	Mechanism of action	Monitoring
Anticonvulsant • Gabapentin • Pregabalin	Neuropathic	GABA analog	- Peripheral edema - Weight gain - Dose adjustment for renal impairment
Antidepressant, tricyclic • Amitriptyline • Nortriptyline	Neuropathic	Inhibit reuptake of serotonin and/or norepinephrine at the presynaptic neuronal membrane pump	- Behavior changes, suicidality - Anticholinergic effects (e.g., constipation, urinary retention)
Antidepressant, serotonin/ norepinephrine reuptake inhibitor • Duloxetine • Venlafaxine	Neuropathic	Inhibits neuronal serotonin and norepinephrine reuptake; weakly inhibits dopamine reuptake	- Behavior changes, suicidality - Avoid use in those with hepatic impairment - Dose adjustment for renal impairment
Nonsteroidal antiinflammatory drug • Ibuprofen • Naproxen • Celecoxib* • Diclofenac • Indomethacin • Ketorolac • Meloxicam • Nabumetone	Nociceptive	Inhibits cyclooxygenase-1 and 2 (COX-1 and 2) enzymes, resulting in decreased formation of prostaglandin precursors; decrease proinflammatory cytokine levels	- Cardiovascular thrombotic events - Gastrointestinal bleeding, ulceration, and perforation - Avoid use in those with renal disease

TABLE 3 Medication management of pain in spinal cord injury—cont'd

Class of medication	Targeted category of pain	Mechanism of action	Monitoring
Nonopioid analgesic • Acetaminophen • Paracetamol	Nociceptive	Not fully known, analgesic effects likely due to activation of CNS descending serotonergic inhibitory pathways	- Hepatotoxicity
Opioid • Buprenorphine • Codeine • Fentanyl • Hydrocodone • Hydromorphone • Methadone • Nalbuphine • Oxycodone • Tramadol	Nociceptive	Binds to opiate receptors in the CNS, inhibiting ascending pain pathways	- CNS depression - Respiratory depression - Hypotension - Constipation
Cannabis	Nociceptive	Activation of the endogenous endocannabinoid system through CB1 and CB2 receptors	- Psychoactive properties - Dizziness - - Nausea, vomiting - Fatigue, drowsiness
Baclofen	Spasticity	GABA agonist at the GABA B receptor	- Lowers seizure threshold - Consider dose adjustment for renal impairment - CNS depression - Urinary retention
Dantrolene	Spasticity	Inhibits the release of calcium from sarcoplasmic reticulum	- Peripherally acting on skeletal muscle - Hepatotoxicity; monitor liver function closely
Alpha 2 adrenergic agonist • Clonidine • Tizanidine	Spasticity	Increasing presynaptic inhibition; reduces facilitation of spinal motor neurons	- Orthostatic hypotension - Drowsiness, dizziness - Bradycardia - Monitor liver function
Benzodiazepine • Diazepam	Spasticity	Facilitates GABA effects on the GABA A receptor	- Caution with concomitant use of opioids - CNS depression - Use with caution in those with renal and hepatic impairment and respiratory disease

Original table: Outline of the mechanism of action of various types of pain medications commonly used for SCI pain.

"Typical" nociceptive pain interventions

SCI individuals, especially those who use a wheelchair to traverse the community are predisposed to upper-body overuse injuries (Requejo et al., 2008) and almost three fourth of individuals with paraplegia have early osteoarthritis of the shoulders (Lal, 1998). Interestingly, shoulder pain and decreased passive range of motion is also present in the acute phase of SCI (Finley et al., 2020). Peripheral nerve stimulation (PNS) is a well-established treatment for poststroke shoulder pain (Wilson et al., 2018) but has not frequently been used for treating SCI-related pain. There is one case report showing improvement in shoulder pain after SCI with PNS use (Mehech, Mejia, Nemunaitis, Chae, & Wilson, 2018).

While literature is lacking with regard to specific interventions for non-SCI-related nociceptive pain, it should be treated just as it would be in the able-bodied population. For instance, tendinopathy is a common condition in the able-bodied population and also has a high prevalence in the SCI population due to overuse, as noted above. Traditionally tendinopathy has been treated with physical therapy, nonsteroidal antiinflammatory medications, and corticosteroid injections which can address the inflammatory component but not the degenerative component of the disorder. Orthobiologics such as platelet-rich plasma (PRP), autologous conditioned serum and stem cells have shown for various degrees of promise (Paoloni, DeVos, Hamilton, Murrell, & Orchard, 2011; Roberts & Rosenbaum, 2012; Wehling et al., 2007) should be considered in the SCI population as they would be in the AB population, if appropriate.

At least 65% of patients with chronic SCI have symptoms of spasticity (Adams & Hicks, 2005) and pain frequently coincides with spasticity (Finnerup, 2017; Holtz, Lipson, Noonan, Kwon, & Mills, 2017). In general, the pain associated with spasticity is felt to be nociceptive muscle pain, similar to that of tetanic contractions. The incidence of spasticity is correlated to incomplete injuries and higher level of injury (Holtz et al., 2017; Skold, Levi, & Seiger, 1999).

Oral antispasticity medications act systemically and can be divided into 3 categories based upon mechanism of action: (1) GABA receptor agonists (e.g., baclofen and diazepam), (2) alpha-2 receptor agonists (e.g., tizanidine), and (3) peripheral acting decouplers of excitation-contraction at the neuromuscular level (e.g., dantrolene) (Burchiel & K Hsu, 2001; Gracies, Nance, Elovic, McGuire, & Simpson, 1997; Kita & Goodkin, 2000; Rode, Maupas, Luaute, Courtois-Jacquin, & Boisson, 2003).

Injection of local chemodenervation agents results in impairment of the nerve (Lui, Sarai, & Mills, 2015). This technique minimizes systemic side effects associated with oral antispasticity medications and is the preferred for treating focal spasticity (Kirshblum, 1999; Lui et al., 2015). The chemodenervation agents most commonly used are phenol, ethanol, local anesthetics, and botulinum toxin (Lui et al., 2015). Botulinum toxin is the most widely used chemodenervation agent and similarly has a temporary effect. Phenol and ethanol exert a semi-permanent effect (Adams & Hicks, 2005; Kirshblum, 1999; Lui et al., 2015).

If oral drug treatment is ineffective in controlling spasticity or is otherwise not tolerated, consideration should be given to intrathecal delivery of baclofen (Burchiel & K Hsu, 2001; Gracies et al., 1997; Kita & Goodkin, 2000; Korenkov, Niendorf, Darwish, Glaeser, & Gaab, 2002). Bypassing the blood-spinal cord barrier allows as much as four times the concentration and lower dose of baclofen to be delivered to the spinal cord relative to an oral dose (Burchiel & K Hsu, 2001; Kita & Goodkin, 2000; Korenkov et al., 2002). Catheter and pump maintenance, appropriate dosage of baclofen, timely refill of the pump, and avoidance of abrupt interruption of baclofen administration are paramount to intrathecal pump management (Burchiel & K Hsu, 2001; Kita & Goodkin, 2000).

Surgery, typically in the form of rhizotomy or tendon lengthening, may be performed to improving function or correcting a deformity related to spasticity in refractory cases (Adams & Hicks, 2005; Ghai, Garg, Hooda, & Gupta, 2013).

Neuromodulation

The presence of pain induces top-down modulation where the various cerebral regions act in unison to upregulate or downregulate pain signals (Martins & Tavares, 2017), mainly through the PAG and RVM (Heinricher et al., 2009). Serotonin, norepinephrine, and dopamine are released at the supraspinal and spinal levels to modulate pain levels and there is a relative deficiency in these peptides after SCI (Bourne et al., 2014).

There is also evidence for dendritic spine remodeling at the level of the spinal cord. After induction of neuropathic pain there is an adaptive and time-dependent response at the level of dorsal horns where neurons develop increased dendritic spine density, redistribute spines closer to the cell body, and increase the spine head surface area, which in turn alters excitatory potential propagation (Benson, Reimer, & Tan, 2020). Animal studies looking at dendritic spines pre- and postneuropathic injury note significant structural anomalies in the steady state fluctuations of spines (Benson et al., 2020). Taken in total, there is accumulating evidence that "pain memory" is at least in part a function carried out by the spinal cord itself and could partly explain the treatment resistant nature of neuropathic pain after SCI (Benson, Fenrich, et al., 2020; Benson, Reimer, et al., 2020; Ji, Kohno, Moore, & Woolf, 2003; Tan & Waxman, 2012; Tan, 2015). Disruption of these intrinsic neuromodulation pathways is postulated to be a unique factor in pain as a side effect of SCI and a differentiator of other peripheral sources of neuropathic pain (Benson, Reimer, et al., 2020; Bourne et al., 2014; Chambel et al., 2020; Heinricher et al., 2009).

Many have hypothesized on medications and interventions that may be of clinical utility given the aforementioned intrinsic neuromodulatory deficits present after SCI. The International Neuromodulation Society defines therapeutic neuromodulation as "the alteration of nerve activity through targeted delivery of a stimulus, such as electrical stimulation or chemical agents, to specific neurological sites in the body." Examples of neuromodulation that have been applied or could potentially be applied in the setting of SCI include SCS, dorsal root ganglion stimulation (DRGS), PNS, and transcranial direct current stimulation (tDCS).

Spinal cord stimulation in SCI

Spinal cord stimulation (SCS) is the most common neuromodulatory intervention in the treatment of pain in patients with SCI. It was first trialed in patients with SCI almost 50 years ago. Previous studies have hypothesized multiple mechanism of action such as gait control theory, dorsal column retrograde stimulation, modulation of centralized pain processing, and even action at the spinal cord level with the alteration of neurotransmitter release (Arle, Carlson, Mei, Iftimia, & Shils, 2014). To date there have been no randomized trials examining efficacy of SCS in patients with SCI. A review of 27 studies cited an average of 30%–40% of pain relief (Lagauche, Facione, Albert, & Fattal, 2009) using various forms of SCS. Traditional SCS utilizes tonic 40–60 Hz stimulation placed on the epidural surface of the dorsal column, often resulting in paresthesia in the distribution that overlaps with the distribution of pain (Chakravarthy, Richter, Christo, Williams, & Guan, 2018). More recently, high-frequency SCS has been applied at low amplitudes resulting in paresthesia free subthreshold sensory activation (Chakravarthy et al., 2018) and has shown promising results for the treatment of refractory neuropathic pain in non-SCI individuals (Kapural et al., 2016). Interestingly, multiple studies looking at SCS have noted concomitant decreased spasticity (Aduddell, Romman, Burlison, & Doulatram, 2015; Dombovy-Johnson, Hunt, Morrow, Lamer, & Pittelkow, 2020; Harandi & Kapural, 2018; Li, Quidgley-Nevares, & Walker, 2011) and pain medication use (Aduddell et al., 2015; Delille, Ahmad, Baeza-Dager, & Mena, 2012; Dombovy-Johnson et al., 2020; Harandi & Kapural, 2018; Li et al., 2011). The potential for multimodal treatment is particularly interesting in this population. Both reviews suggest individuals with incomplete tetraplegia or paraplegia may benefit more than complete injuries (Dombovy-Johnson et al., 2020; Lagauche et al., 2009).

Other forms of neuromodulation

Other forms of neuromodulation for pain are less common in SCI. tDCS over the motor cortex has shown modest decreases in pain (Ngernyam et al., 2015; Soler et al., 2010). However, both studies had small sample sizes and a study by Wrigley et al. (2013) found no improvement in longstanding neuropathic pain after SCI with the use of tDCS suggesting the effect is either less robust or potentially more beneficial in the acute to subacute phase. PNS, as noted previously, has been described as a treatment for post-SCI shoulder pain from chronic overuse injuries.

DRGS is a similar in nature to SCS except the leads are placed on the dorsal root ganglion instead of the epidural space. Stimulation of the DRG is thought to still work in a downstream effect on the spinal cord but has been particularly helpful with the treatment of regional neuropathic pain, such as complex regional pain syndrome (Harrison, Epton, Bojanic, Green, & FitzGerald, 2018). However, there is a case report of bilateral L2 DRGS improving spasticity and low back pain after SCI (Soloukey et al., 2020).

Mini-dictionary of terms

Nociceptive pain: Pain from a noxious or potentially harmful stimulus. Nociceptive pain is well localized and corresponds to damage to skin, joints, muscle, bone, or connective tissue. It is typically described as sharp, achy, throbbing, etc.

Visceral pain: Pain from internal organs. Visceral pain is generally poorly localized and described as deep, squeezing, pressure, or aching.

At-level neuropathic pain: Pain in a dermatomal distribution that reflects damage to the spinal cord at the level of the individual's spinal cord injury (SCI). Occasionally, this can feel "band-like" or "squeezing," but often feels like "numbness," "pins-and-needles," or "tingling."

Below-level neuropathic pain: Pain that corresponds to damaged nerves in the spinal cord that typically provide sensation to an area below the level of the individual's SCI. Below-level neuropathic pain is typically described as "numbness," "pins-and-needles," or "tingling."

Neuromodulation: the alteration of nerve activity through targeted delivery of a stimulus, such as electrical stimulation or chemical agents, to specific neurological sites in the body.

Spinal cord stimulation (SCS): Implantable device where leads are placed in the epidural space overlying the dorsal columns. SCS devices send mild pulses of electricity at various frequencies depending on the device and settings that help dampen neuropathic pain.

Dorsal root ganglion stimulator (DRGS): Similar to an SCS but is instead implanted with the leads on the dorsal root ganglion. In general, DRGS is favored for regional pain.

Peripheral nerve stimulator (PNS): A permanent or temporary implantable lead that is placed in close proximity to a peripheral nerve. PNS devices stimulate mixed motor and sensory nerves at submaximal intensity with the goal of decreasing pain that is related to irritation, damage, or improper function of a single nerve.

Transcranial direct current stimulation (tDCS): constant, low direct current electrical stimulus that is applied to specific cortical areas through surface scalp electrodes.

Supraspinal pathways: Ascending and descending pathways that relay information to, from, and through the spinal cord. Disruption of different supraspinal pathways plays a critical role in many aspects of SCI, including pain.

Key facts of pain after SCI

- Sixty-five percent to eighty percent of individuals with SCI live with chronic pain.
- One third of individuals with chronic pain after SCI rate this pain as severe and more than half note that pain interferes with their daily function independent of their other SCI deficits such as paralysis.
- Level of injury does not seem to influence the degree of associated pain, although there is some evidence that incomplete spinal cord injuries are more painful.
- Up to 80% of those with pain and SCI find PT to be helpful.
- Pregabalin is the only FDA-approved treatment for neuropathic SCI pain, although antiepileptic and antidepressant medications are commonly used and supported by literature.
- Neuromodulation is currently lacking evidence, but small studies are promising and a future direction of additional research.

Summary points

- The PAG is a central pain relay center that modulates pain signals to the RVM and spinal cord effectively upregulating and downregulating pain signals.
- SCI disrupts this relay and leads to a relative deficiency in supraspinal inhibition and deficiency in spinal levels of serotonin, norepinephrine, and dopamine.
- Neuropathic pain after SCI is commonly treated with membrane-stabilizing agents.
- Nociceptive pain after SCI should be treated like nociceptive pain in the AB population.
- Neuromodulation is an interesting treatment possibility, although further research is needed.

SCI	spinal cord injury
TSCI	traumatic spinal cord injury

Introduction

A pressure injury (PI), also known as pressure ulcer, pressure sore, bedsore, or decubitus ulcer, is defined as a circumscribed injury to the skin and/or underlying tissue due to pressure, or shear combined with pressure, causing ischemia, cell death, and tissue necrosis (European Pressure Ulcer Advisory Panel, National Pressure Injury Advisory Panel and Pan Pacific Pressure Injury Alliance, 2019; Ham, Schoonhoven, Schuurmans, & Leenen, 2017). It may present as an open wound or intact skin. The most commonly used pressure injury classification system, based on the extent of tissue involvement, is the one developed by the National Pressure Injury Advisory Panel (NPIAP) (Table 1) (Fig. 1) (European Pressure Ulcer Advisory Panel, National Pressure Injury Advisory Panel and Pan Pacific Pressure Injury Alliance, 2019). In order to accurately describe PI, staging can only be done after proper cleansing of the wound and exposure debridement of slough or eschar, thus sometimes postponing final staging of certain PI where necrotic tissue is present in the wound bed (European Pressure Ulcer Advisory Panel, National Pressure Injury Advisory Panel and Pan Pacific Pressure Injury Alliance, 2019). PI assessment should also include dimensions, tissue quality, quantity and quality of exudate, wounds edges, presence of tunneling or undermining, peri-wound condition, odor and signs of infections, or other complications (European Pressure Ulcer Advisory Panel, National Pressure Injury Advisory Panel and Pan Pacific Pressure Injury Alliance, 2019).

TABLE 1 Pressure injury stages according to the National Pressure Injury Advisory Panel (NPIAP).

Stage 1	Intact skin with a circumscribed zone of non-blanchable erythema
Stage 2	Partial-thickness skin damage where the dermis is exposed
Stage 3	Full-thickness skin damage where the fat is exposed, granulation tissue is present and wounds edges are rolled
Stage 4	Full-thickness skin damage where fascia, muscle, tendon, ligament, cartilage, or bone is exposed
Unstageable	Full-thickness skin damage where a Stage 3 or Stage 4 is suspected but cannot be determined due to presence of necrotic tissues
Deep tissue pressure injury	Intact or damaged skin with a circumscribed non-blanchable purple or dark red zone, or presence of epidermal separation exposing a dark wound bed or blood-filled blister

Pressure injury classification system, based on the extent of tissue involvement, developed by the National Pressure Injury Advisory Panel (NPIAP) (European Pressure Ulcer Advisory Panel, National Pressure Injury Advisory Panel and Pan Pacific Pressure Injury Alliance, 2019).

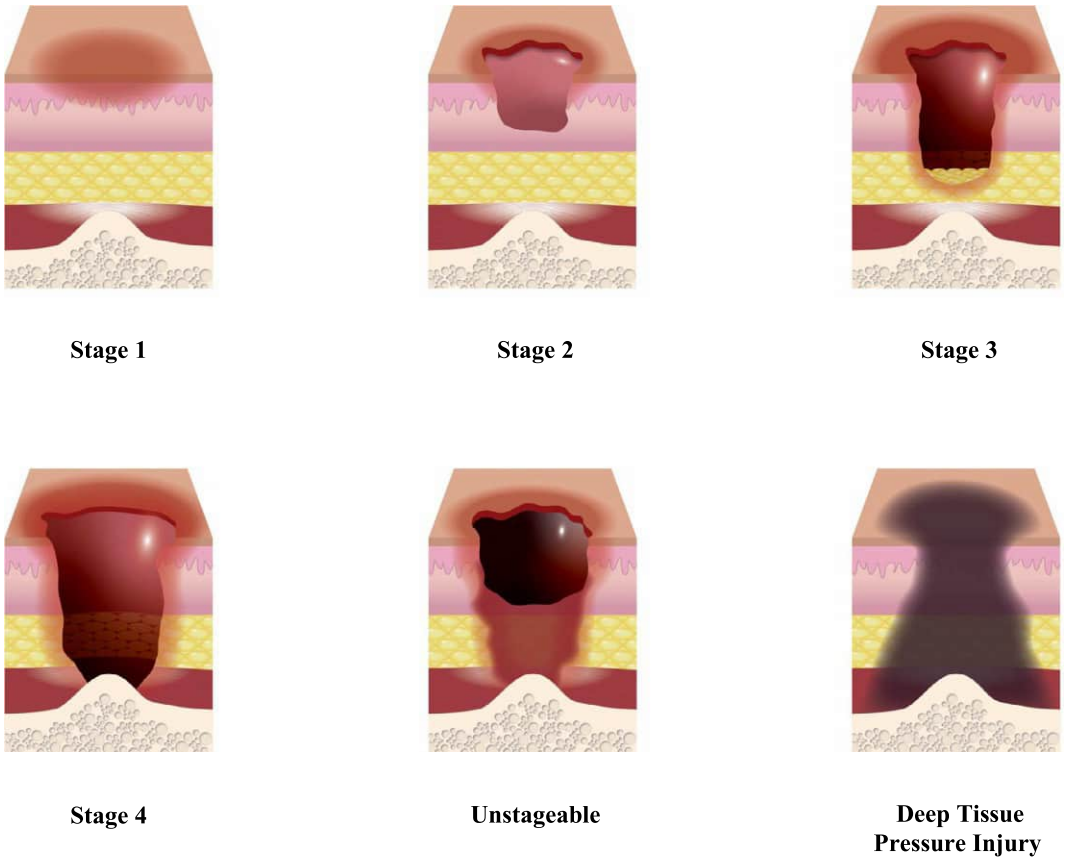

FIG. 1 Pressure injury stages. Schematic drawings of the different pressure injury stages (illustrated by Bréval Le Mestique).

Due to risk factors inherent to their condition, such as decreased sensation and mobility limitations, spinal cord injury (SCI) patients are at higher risk of developing a PI when compared to the general population (European Pressure Ulcer Advisory Panel, National Pressure Injury Advisory Panel and Pan Pacific Pressure Injury Alliance, 2019; Houghton & Campbell, 2013). Their occurrence can have significant physical, psychological, and functional consequences and may hinder independence, self-esteem, social well-being, and overall quality of life (Kisala, Tulsky, Choi, & Kirshblum, 2015; Street, Noonan, Cheung, Fisher, & Dvorak, 2015). Their prevention is therefore essential and should be an integral part of the medical and rehabilitation goals.

Pathophysiology of pressure injuries

Pressure and shear

Pressure and shear forces, especially over bony prominences or due to medical devices or other objects, are the principal factors associated with the development of PI. As a result of these forces, the loaded soft tissues will deform, causing strains and stresses which, if sustained, may lead to tissue damage (European Pressure Ulcer Advisory Panel, National Pressure Injury Advisory Panel and Pan Pacific Pressure Injury Alliance, 2019). Sustained soft tissue deformation leads to hypoxia, reduced lymphatic flow as well as reduced nutrient supply and removal of metabolic waste products which in turn causes cell death and tissue damage (Gawlitta, Li, et al., 2007; Gawlitta, Oomens, Bader, Baaijens, & Bouten, 2007; Gray, Worsley, Voegeli, & Bader, 2016). Pressure intensity and duration as well as tissue tolerance and vascular perfusion also play a significant role (European Pressure Ulcer Advisory Panel, National Pressure Injury Advisory Panel and Pan Pacific Pressure Injury Alliance, 2019).

Both low mechanical load for a long period and high load for a short period of time may result in tissue damage (Breuls, Bouten, Oomens, Bader, & Baaijens, 2003; Gawlitta, Li, et al., 2007; Gawlitta, Oomens, et al., 2007). To date, no universal safe tissue interface pressure threshold has been established, thus highlighting the importance of evaluating and addressing

all possible PI risk factors as tissue interface pressure measurement alone is insufficient (Coleman et al., 2014; Groah, Schladen, Pineda, & Hsieh, 2015; Oomens, Loerakker, & Bader, 2010).

Tissue tolerance

Different tissue types have varying degrees of tolerance to deformation with muscle tissues being more susceptible to damage than fat and skin (Salcido et al., 1994). The orientation of shear forces is also important as skin is more resistant to forces occurring in alignment with collagen fiber bundles than when they are applied perpendicular to fiber bundles (Destrade, Gilchrist, Prikazchikov, & Saccomandi, 2008).

In addition, soft tissue tolerance may be affected by many factors such as perfusion, micro-climate as well as patients and tissue characteristics (European Pressure Ulcer Advisory Panel, National Pressure Injury Advisory Panel and Pan Pacific Pressure Injury Alliance, 2019). For example, trauma victims have an increased risk of developing PI, with 45.8% of them developing within 48 h of admission (Ham et al., 2017). Because of the risk factors inherent to their condition, such as immobility, decreased autonomic control, hyper catabolic responses, and lack of protective response due to sensorimotor deficits (Houghton & Campbell, 2013; Michel et al., 2012), patients with traumatic spinal cord injury (TSCI) are almost 14 times more likely to develop a PI than other trauma patients (Grigorian et al., 2017).

Prevalence, impact, and cost of pressure injuries in patients with SCI

Pressure injuries (PI) are one of the most common complications following SCI with up to 80% of patients developing a PI at some point during their lifetime (Garber, Rintala, Hart, & Fuhrer, 2000; Kirshblum & Lin, 2018). Compared to other rehabilitation phases, the acute hospitalization represents the period with the highest PI risk (Brienza, Krishnan, Karg, Sowa, & Allegretti, 2018) with a prevalence ranging from 2.7% to 57% when compared to 15% to 54% in the chronic SCI stage (Brienza et al., 2018; Gelis et al., 2009b; van der Wielen, Post, Lay, Glasche, & Scheel-Sailer, 2016). Factors such as severe neurological deficits, altered level of consciousness, and multiple concomitant traumatic injuries lead to prolonged periods of immobility and decreased general health status, putting patients at higher risk of PI during acute care (Ham et al., 2017).

Most common locations and severity

During acute care and rehabilitation, when patients spend more time in a supine position, the most commonly affected areas include the ischium (28%), the sacrum (17%–27%), trochanters (12%–19%), and heels (9%–18%) (Kruger, Pires, Ngann, Sterling, & Rubayi, 2013). During the chronic stage, when patients spend more time in a sitting position, the ischium or perineum (48.3%), sacrum (37.2%), and trochanters (14.5%) are more susceptible to PI (Guihan et al., 2016).

Molano et al. have shown that in their cohort, the majority of PIs occurring during acute care were stage 2 and 3 (Molano Alvarez et al., 2004). For their part, Powers et al. have shown a predominance of stages 1 and 2 (Powers, Daniels, McGuire, & Hilbish, 2006). In a recent study, Ham et al. suggested that the number of stage 1 PI may be underestimated due to the absence of skin loss, making their identification sometimes more difficult and by the fact that they rapidly progress to more severe stages if not addressed (Ham et al., 2017).

Impact

Patients with TSCI who develop a PI during acute hospitalization have higher complication rates, significantly longer length of stay, and higher risk of recurrence (Klotz, Joseph, Ravaud, Wiart, & Barat, 2002; Street et al., 2015; Verschueren et al., 2011). Complications of PI such as wound infection, cellulitis, septic arthritis, osteomyelitis, sepsis, and malignant transformation (Marjolin's ulcers) may also occur (Houghton & Campbell, 2013). In some cases, PI can lead to surgical procedures, amputation, and sometimes even death due to an infection (Houghton & Campbell, 2013). Indeed, 7%–8% of patients with TSCI who develop a PI die from associated complications (Richards, Waites, Chen, Kogos, & Schmitt, 2004). PI also limit long-term functional outcome by interfering with rehabilitation (Hastings, Ntsiea, & Olorunju, 2015; Post, Dallmeijer, Angenot, van Asbeck, & van der Woude, 2005). Following the acute hospitalization, patients are at higher risks of developing a PI during the first year post-SCI or more than 25 years post-injury (National Spinal Cord Injury Statistical Center, 2019). After urinary tract infections, PI represent the second most common cause of re-hospitalization during the first year post-TSCI as well as in the following years, accounting for 11.3% of

re-hospitalizations at 1 year, 14.6% at 5 years, 17.5% at 10 years, and 21.3% at 20 years post injury (National Spinal Cord Injury Statistical Center, 2019).

Cost

It has been estimated that one-quarter of the cost of care for patients with SCI is associated with PI and thus represent a significant preventable financial burden. In 2013, in Canada, the occurrence of PI resulted in an additional $18,758 to the cost of acute hospitalization following TSCI (White et al., 2017). In the United Kingdom, PI treatment ranges from $2000 to $18,000 (Bennett, Dealey, & Posnett, 2004) while in the United States, annual health care costs per patient was estimated to be $73,021 higher for patients with PI when compared to patients without PI (Stroupe et al., 2011). Finally, a recent systematic review showed that interventions to prevent PI occurrence were considerably less expensive than the interventions for their treatment (Demarré et al., 2015).

Structural and physiological changes following SCI

Following SCI, multiple structural and physiological changes occur, decreasing the body's ability to maintain skin integrity, increasing the risk of tissue breakdown, and thus putting patients at higher risk of developing PI (Table 2).

Skin

Thinning of skin at load-bearing sites, decrease in skin distensibility in the remaining skin tissues, decrease in fibroblast activity, and increase in collagen catabolism are seen in patients with SCI with greater changes in skin distensibility,

TABLE 2 Structural and physiological changes following SCI.

Skin changes	– Skin thinning at load-bearing sites – Decrease in skin distensibility in the remaining skin tissues – Decreased fibroblast activity – Greater collagen catabolism – Decrease in type I to type III collagen ratio in skin below injury level
Disuse-induced muscle atrophy	– Fibers thinning – Decrease in numbers of slow-twitch fibers and increase in fast-twitch fibers below the level of injury – Increase in intra-muscular fat causing greater intra-muscular shear stresses at interfaces between muscle and intra-muscular fat tissues
Bone changes	– Flattening of ischial tuberosities due to chronic exposure to sitting mechanical loading coupled with cortical bone mass loss, shifting load transfer from weight-bearing ischial tuberosities to overlying soft tissues
Changes in macro- and micro-vasculature	– Vasodilation and impairment in tissue perfusion below injury level – Decrease in the density of both alpha- and beta-adrenergic receptors in the skin below injury level resulting in abnormal vascular response – Decrease in number and size of capillaries feeding skeletal muscle fibers – Decrease in lower limbs cutaneous blood when sitting
Chronic inflammation and immune function	– Decrease healing response by depression of immune system function – Chronic tissue inflammation decreases tissue tolerance and repair capacity further increasing tissue breakdown risk
Temperature dysregulation	– Increase in resting skin temperature and decrease in skin temperature reactivity in lower limbs
Sensory impairments	– Sensory deficits resulting in lack of protective response allowing the progression from ischemia to tissue breakdown and necrosis

Summary of the multiple structural and physiological changes occurring following SCI predisposing to pressure injuries (Carda, Cisari, & Invernizzi, 2013; Cotie, Geurts, Adams, & MacDonald, 2011; Cruse et al., 2000; Deitrick, Charalel, Bauman, & Tuckman, 2007; European Pressure Ulcer Advisory Panel, National Pressure Injury Advisory Panel and Pan Pacific Pressure Injury Alliance, 2019; Gefen, 2018; Gorgey & Dudley, 2007; Kirshblum & Lin, 2018; Kruger et al., 2013; Lachenbruch, Tzen, Brienza, Karg, & Lachenbruch, 2013; Linder-Ganz et al., 2008; Michel et al., 2012; Park, Seo, Han, & Lee, 2011; Patterson, Cranmer, Fisher, & Engel, 1993; Rappl, 2008; Rodriguez, Claus-Walker, Kent, & Stal, 1986; Rodriguez & Markowski, 1995; Ruschkewitz & Gefen, 2011; Scelsi, 2001; Schwab, Zhang, Kopp, Brommer, & Popovich, 2014; Sopher, Nixon, Gorecki, & Gefen, 2011; Thorfinn, Sjöberg, & Lidman, 2002; Wilczweski et al., 2012; Wu & Bogie, 2013; Yalcin, Akyuz, Onder, Unalan, & Degirmenci, 2013; Zeevi, Levy, Brauner, & Gefen, 2018).

elasticity, and viscoelasticity observed in patients with longer time elapsed since SCI (Park et al., 2011; Yalcin et al., 2013). A decrease in type I to type III collagen ratio is also seen in the skin below the level of injury which may further contribute to skin fragility following SCI by decreasing tensile strength (Rodriguez & Markowski, 1995).

Muscle and bone

In addition to normally occurring age-related muscle atrophy (Roubenoff, 1999), patients with SCI undergo significant disuse-induced muscle atrophy below the level of injury (Gorgey & Dudley, 2007) with greater atrophy seen at the level of ischial tuberosities (Wu & Bogie, 2013). Muscle atrophy decreases natural protective cushioning over bony prominences, increasing PI risk (Linder-Ganz & Gefen, 2009). Thinning of the fibers, decrease in the numbers of slow-twitch fibers, and increase in fast-twitch fibers may be seen as early as 4–6 weeks following TSCI (Carda et al., 2013). An increase in intra-muscular fat is also observed (Gorgey & Dudley, 2007), causing greater intra-muscular shear stresses at interfaces between muscle and intra-muscular fat tissues (Sopher et al., 2011; Wu & Bogie, 2013), thus further increasing PI risk. In addition, due to chronic exposure to sitting mechanical loading coupled with cortical bone mass loss, ischial tuberosities tend to flatten, shifting load transfer from weight-bearing ischial tuberosities to overlying soft tissues (Linder-Ganz et al., 2008).

Macro- and micro-vasculature

Changes in macro- and micro-vasculature also occur partly due to alteration in autonomic control. First, a loss of vascular tone is seen below the lesion resulting in vasodilation and thus decreasing vascular resistance and impairing tissue perfusion (Rappl, 2008). Also, a decrease in the density of both alpha- and beta-adrenergic receptors is observed in the skin below the level of injury in patients with longer-standing injuries resulting in abnormal vascular response (Rodriguez et al., 1986). When compared to patients without SCI, lower limbs cutaneous blood flow has been shown to decrease by at least 50% in patients with SCI when sitting (Deitrick et al., 2007). A decrease in number and size of capillaries feeding skeletal muscle fibers is also seen, making these muscles more susceptible to ischemia, especially during episodes of low blood pressure (Ruschkewitz & Gefen, 2011; Scelsi, 2001). Moreover, when compared to healthy controls, patients with SCI tend to have significantly higher sitting pressure and significantly lower transcutaneous oxygen tension levels, followed by slower reactive hyperemia when unloaded, translating into a lower rate of reperfusion (Patterson et al., 1993; Thorfinn et al., 2002). This therefore suggests a longer recovery time is required for patients with SCI following loading periods to allow appropriate tissue re-oxygenation before reloading the area.

Inflammation and immune function

A chronic systemic inflammatory response occurs following trauma and may predispose patients with SCI to PI and decrease healing response by depressing immune system function (Cruse et al., 2000; Schwab et al., 2014). Compromise in tissue perfusion paired with chronic tissue inflammation decrease tissue tolerance and repair capacity further increasing tissue breakdown risk (Gefen, 2018).

Temperature

Due to loss of autonomic control, temperature dysregulation is also common in patients with SCI. Cotie et al. have shown that an increase in resting skin temperature and a reduced skin temperature reactivity are seen in the lower limbs of patients with SCI (Cotie et al., 2011). In addition, urinary and/or fecal incontinence is common in patients with SCI further increasing the risk of moisture and maceration (Kirshblum & Lin, 2018; Wilczweski et al., 2012). An increase in body temperature, especially when coupled with excessive humidity and maceration, has a profound effect on tissue tolerance to damage and thus must not be overlooked especially when addressing support surfaces and medical devices (Lachenbruch et al., 2013; Wilczweski et al., 2012; Zeevi et al., 2018).

Sensory impairments

Finally, sensory deficits associated with SCI results in a lack of protective response due to decreased awareness of tissue injury thus allowing the progression from ischemia to tissue breakdown and necrosis (European Pressure Ulcer Advisory

Panel, National Pressure Injury Advisory Panel and Pan Pacific Pressure Injury Alliance, 2019; Kruger et al., 2013; Michel et al., 2012).

Risk assessment tools

The purpose of a risk assessment tool is to identify and stratify individuals who are more susceptible to PI occurrence in order to better evaluate and address risk factors and the adequacy of preventive measures. Although the SCIPUS and SCIPUS-A scales, which were specifically developed to assess patients with SCI during acute hospitalization and rehabilitation, show promise, they haven't demonstrated acceptable accuracy and, thus at this point, cannot be recommended (Mortenson & Miller, 2008). The two most common scales used to assess PI risk are the Braden Scale and the Norton Scale. The Braden Scale measures six domains: sensory perception, moisture, activity, mobility, nutrition, and friction/shear. Each domain is scored on a scale of 1–4 except for friction/shear which is score from 1 to 3. The total score thus ranges from 6 to 23, with lower score meaning greater risk for skin breakdown. Preventative measures should be put in place in patients with a score of 18 or less. The Norton Scale measures five domains: physical condition, mental condition, activity, mobility, and continence. Each domain is scored on a scale of 1–4 which are then summed to give a total score ranging from 5 (worst prognosis) to 20 (best prognosis). Similarly, preventive measures should be put in place in patients with a score of 16 or less (Mortenson & Miller, 2008).

Risk factors associated with pressure injuries in patients with traumatic spinal cord injury

As discussed, susceptibility, severity, and extent of PI depend on type, magnitude, and duration of mechanical load, but also on the mechanical properties of the tissue, tissue and bone morphology, tissue repair capacity as well as transport and thermal properties of tissues (Coleman et al., 2014). In addition to the structural and physiological changes occurring following an SCI described in the previous section, many other risk factors have been shown to influence key components of PI development thus making patients with TSCI even more vulnerable to PI. These may be classified as non-modifiable factors if they cannot be addressed and optimized, and modifiable factors if they can be reduced or changed (Table 3).

Non-modifiable factors

Patient characteristics

Whether older age (Brienza et al., 2018; Di Prinzio et al., 2019; Gelis et al., 2009a, 2009b; Ham et al., 2017; Marin et al., 2013; Wilczweski et al., 2012) and sex (Ash, 2002; Di Prinzio et al., 2019; Gelis et al., 2009a, 2009b; Sheerin et al., 2005; Wilczweski et al., 2012) are significant risk factors to PI development is still debated in the literature. However, it has been shown that 10–20 years post injury, SCI accelerates the physical and functional decline associated with aging which may further increase PI risk (Menter & Hudson, 1995). Although some studies have shown that race may be associated with PI occurrence (Chen et al., 2005; Guihan et al., 2008; Saunders et al., 2010), a recent study found that when controlled for socioeconomic status and healthcare access, race becomes a non-significant risk factor (Saunders et al., 2012). Indeed, patients with SCI with lower household income (Jorge et al., 2018; Saunders et al., 2010; Saunders et al., 2012), who are unemployed (Klotz et al., 2002; Krause et al., 2001; Krause & Broderick, 2004), who have lower educational levels (Chen et al., 2005; Klotz et al., 2002; Krause et al., 2001), and who are single (Chen et al., 2005; Gelis et al., 2009b; Krause et al., 2001) tend to be at higher risk of developing a PI.

Injury characteristics and associated conditions

The completeness of the TSCI (according to the International Standards for Neurological Classification of Spinal Cord Injury (ISNCSCI) (Kirshblum et al., 2011)) is significantly associated with greater PI risk (Brienza et al., 2018; Di Prinzio et al., 2019; Gelis et al., 2009a, 2009b; Gour-Provencal et al., 2020; Grigorian et al., 2017; Joseph & Nilsson Wikmar, 2016; Li et al., 2017; Marin et al., 2013; Marion et al., 2017; Verschueren et al., 2011). Higher levels of neurological injury may also be a higher risk of PI however this is still debated in the literature (Ash, 2002; Chen et al., 2005; Di Prinzio et al., 2019; Gelis et al., 2009b; Gour-Provencal et al., 2020; Grigorian et al., 2017; Krause & Broderick, 2004; Marin et al., 2013; Marion et al., 2017; Sheerin et al., 2005; Verschueren et al., 2011). Higher levels and complete injuries are associated with greater sensorimotor deficits, decreased autonomic control impairing micro-vascular response, greater risk of developing nutritional deficiencies, and more severe mobility limitations, all of which predispose to PI development

TABLE 3 Risk factors associated with pressure injuries in patients' traumatic spinal cord injury.

Non-modifiable risk factors	Modifiable risk factors
Older age (still debated)	Obesity or being underweight
Lower household income Unemployment Lower educational levels Single	Smoking and alcohol abuse (still debated) Substance abuse
Greater severity of injury (motor complete vs incomplete)	Dysthymic symptoms Schizophrenia Personality disorders Neurocognitive changes Delirium
Higher neurological level of injury (tetraplegia vs paraplegia) (still debated)	Medication use for pain, insomnia, spasticity, or stress
Poorer functional status	Longer admission delay between trauma site and the emergency department Longer time spent with immobilization device (>6 h) Longer surgical duration (>6 h)
Greater trauma severity and presence of concomitant traumatic injuries	Longer acute care length of stay
Hypotension, hypovolemic, or hemorrhagic shock, with prolonged periods of mean arterial pressure of <70 mmHg	Care management in a non-SCI-specialized center Surgical delay of >24 h
Mechanical ventilation	Medical complications
Patients with longer-standing TSCI, >25 years post SCI	Hypoalbuminemia Malnutrition Anemia (still debated)
Previous history of PI (stage 3 or 4 or requiring surgery)	Immobility in the frail Poor bed and wheelchair positioning
Presence of comorbidities (diabetes, metabolic syndrome, cardiovascular disease, peripheral vascular disease, pulmonary diseases, and renal disease)	No access to appropriate support surfaces Inappropriate turning in bed schedule Poor compliance Little or non-knowledge of PI prevention strategies

Summary of the non-modifiable and modifiable risk factors associated with pressure injuries in patients traumatic spinal cord injury (Ash, 2002; Bourassa-Moreau, Mac-Thiong, Feldman, Thompson, & Parent, 2013; Brienza et al., 2018; Chen, Devivo, & Jackson, 2005; DeJong et al., 2014; Di Prinzio et al., 2019; European Pressure Ulcer Advisory Panel, National Pressure Injury Advisory Panel and Pan Pacific Pressure Injury Alliance, 2019; Garber et al., 2000; Gater, 2007; Gelis et al., 2009a, 2009b; Gour-Provencal, Mac-Thiong, Feldman, Bégin, & Richard-Denis, 2020; Grigorian et al., 2017; Groah et al., 2015; Guihan et al., 2008, 2016; Ham et al., 2017; Ham, Schoonhoven, Schuurmans, & Leenen, 2014; Hatchett, Mulroy, Eberly, Haubert, & Requejo, 2016; Houghton & Campbell, 2013; Jorge, White, & Agarwal, 2018; Joseph & Nilsson Wikmar, 2016; Klotz et al., 2002; Krause & Broderick, 2004; Krause, Vines, Farley, Sniezek, & Coker, 2001; Krishnan et al., 2017; Le Fort, Espagnacq, Perrouin-Verbe, & Ravaud, 2017; Li, DiPiro, Cao, Szlachcic, & Krause, 2016; Li, DiPiro, & Krause, 2017; Marin, Nixon, & Gorecki, 2013; Marion et al., 2017; Mathew, Samuelkamaleshkumar, Radhika, & Elango, 2013; Michel et al., 2012; Morita, Yamada, Watanabe, & Nagahori, 2015; Parent, Barchi, LeBreton, Casha, & Fehlings, 2011; Ploumis et al., 2011; Rabadi & Vincent, 2011; Richard-Denis, Thompson, Bourassa-Moreau, Parent, & Mac-Thiong, 2016; Saunders & Krause, 2010; Saunders, Krause, & Acuna, 2012; Saunders, Krause, Peters, & Reed, 2010; Scelsi, 2001; Sheerin, Gillick, & Doyle, 2005; Smith, Guihan, LaVela, & Garber, 2008; Tate, Forchheimer, Krause, Meade, & Bombardier, 2004; van der Wielen et al., 2016; Verschueren et al., 2011; Wilczweski et al., 2012).

(Brienza et al., 2018; Ham et al., 2017; Kruger et al., 2013; Mathew et al., 2013; Michel et al., 2012). Similarly, patients with SCI with poorer functional status tend to be more susceptible to PI (Garber et al., 2000; Mathew et al., 2013; Saunders et al., 2010; Verschueren et al., 2011). According to the National Spinal Cord Injury Statistical Center patients with complete tetraplegia have the highest risk of developing a PI during acute care and rehabilitation, followed by patients with complete paraplegia, incomplete tetraplegia and incomplete paraplegia (National Spinal Cord Injury Statistical Center, 2006).

Greater trauma severity (Ham et al., 2014, 2017) as well as the presence of concomitant traumatic injuries such as fractures, organ trauma, and traumatic brain injury increase the risk of developing a PI, as they are generally associated with lower tissue perfusion pressure, longer surgical times, and a more precarious health status (Ash, 2002; European Pressure Ulcer Advisory Panel, National Pressure Injury Advisory Panel and Pan Pacific Pressure Injury Alliance, 2019; Ham et al., 2014, 2017). Hypotension, hypovolemic or hemorrhagic shock, with prolonged periods of mean arterial pressure of less than 70 mmHg during hospitalization is also associated with PI onset (Gelis et al., 2009a; Wilczweski et al., 2012). PI incidence significantly increases in patients requiring mechanical ventilation (Brienza et al., 2018; Ham et al., 2014).

Patients with longer-standing TSCI, especially those more than 25 years post injury, have a higher risk of PI occurrence (Gelis et al., 2009b; van der Wielen et al., 2016) and a greater susceptibility to PI management requiring recurrent hospital admissions (Goodman, Schindler, Washington, Bogie, & Ho, 2014). Similarly, patients with SCI with a previous history of PI, especially those with stage 3 or 4 or those requiring surgery, are at higher risk of PI recurrence (DeJong et al., 2014; Le Fort et al., 2017; Verschueren et al., 2011).

Comorbidities

The presence of comorbidities such as diabetes, metabolic syndrome, cardiovascular disease, peripheral vascular disease, pulmonary diseases, and renal disease has also been associated with PI onset (Ash, 2002; Di Prinzio et al., 2019; Gelis et al., 2009b; Guihan et al., 2008, 2016; Houghton & Campbell, 2013; Li et al., 2016; Marin et al., 2013; Michel et al., 2012).

Modifiable factors

Lifestyle habits, medication, and psychological factors

Some patients with SCI are at higher risk of obesity (Gater, 2007; Hatchett et al., 2016; Scelsi, 2001), resulting in greater compressive forces on weight-bearing sites, increasing PI susceptibility (Elsner & Gefen, 2008; Sopher, Nixon, Gorecki, & Gefen, 2010). Patients who are underweight are also at higher risk of PI (Krause et al., 2001).

Although smoking has been shown to have adverse effects on PI healing (Lane, Selleck, Chen, & Tang, 2016) by decreasing arterial oxygen tension, it is still debated in the literature whether it is a significant risk factor for PI occurrence (Di Prinzio et al., 2019; Gelis et al., 2009a, 2009b; Krause et al., 2001; Li et al., 2016, 2017; Marin et al., 2013) similar to alcohol abuse (Krause et al., 2001; Li et al., 2016, 2017; Tate et al., 2004). Substance abuse may increase the risk of self-negligent behaviors and thus has been observed to be a significant PI risk factor (Tate et al., 2004).

Patients with SCI and dysthymic symptoms, schizophrenia, personality disorders, neurocognitive changes, or delirium are all at higher risk of PI development (Di Prinzio et al., 2019; Gelis et al., 2009b; Krause & Broderick, 2004; Smith et al., 2008). The use of prescription medication for pain, insomnia, spasticity or stress may also increase PI susceptibility (Di Prinzio et al., 2019; Krause & Broderick, 2004; Li et al., 2017; Saunders & Krause, 2010).

Patient management and care

Admission delay between trauma site and the emergency department, longer time spent with an immobilization device (backboard, cervical collar) as well as longer duration of surgery have all been shown to drastically increase PI occurrence, especially after 6 h (European Pressure Ulcer Advisory Panel, National Pressure Injury Advisory Panel and Pan Pacific Pressure Injury Alliance, 2019; Ham et al., 2014; Parent et al., 2011). These factors lead to longer periods of immobility, decreasing tissue oxygenation over bony prominences and increasing temperature and humidity under the devices, thereby increasing PI susceptibility (Ham et al., 2014). It has also been suggested that patients who wear immobilization devices for longer periods of time tend to be patients with more severe injuries further increasing PI risk (Ham et al., 2014).

Receiving care in a SCI-specialized center and a surgical delay of less than 24 h are shown to be protective factors (Bourassa-Moreau et al., 2013; Parent et al., 2011; Ploumis et al., 2011; Richard-Denis et al., 2016). This can be explained by the fact that the SCI-specialized centers comprise qualified nurses and therapists, who better understand the specifics of the overall management of patients with SCI (Parent et al., 2011). Shorter acute care length of stay has also been associated with fewer PI (Ploumis et al., 2011; van der Wielen et al., 2016).

The occurrence of medical complications such as urinary tract infections and pneumonia also increases PI risk (Brienza et al., 2018; Gour-Provencal et al., 2020; Joseph & Nilsson Wikmar, 2016; Krishnan, Vodovotz, et al., 2017) as they cause decreased tissue oxygenation, decreased mobility, and an impaired inflammatory response, thereby compromising the patient's immunity and further predisposing them to PI (Brienza et al., 2018; Krishnan, Karg, Boninger, & Brienza, 2017; Krishnan, Vodovotz, et al., 2017). Hypoalbuminemia and malnutrition have also been associated with higher PI risk while low hemoglobin is still debated (Di Prinzio et al., 2019; Marin et al., 2013; Rabadi & Vincent, 2011).

Prevention strategies and patient compliance

Immobility in the frail, poor bed and wheelchair positioning and repositioning have been shown to increase PI risk (Groah et al., 2015). Access to appropriate support surface (Morita et al., 2015), turning in bed schedule, knowledge, and compliance to PI prevention strategies may be protective factors (Garber et al., 2000; Mathew et al., 2013; Morita et al., 2015).

Conclusion

Despite medical advances and improvement in knowledge through the years, pressure injuries remain a serious challenge throughout the acute hospitalization, rehabilitation, and community reintegration stages for both patients with TSCI and medical professionals. The repercussions are significant on the physical, psychological, functional, and financial states, and thus their prevention is crucial. Better identifying and addressing factors contributing to their occurrence is the first step toward improving patient outcome and quality of life. Although various factors have been identified as potential PI risk factors, no single component can explain PI occurrence on its own but rather a complex interaction of different factors, therefore highlighting the importance of a comprehensive management and care plan.

Applications to other areas of neuroscience

As reviewed in this chapter, due to risk factors inherent to their condition, patients with traumatic spinal cord injury (TSCI) are at higher risk of developing a pressure injury (PI). A recent retrospective analysis using data from the National Trauma Data Bank showed that, when adjusted for covariates, spinal cord injury was the strongest predictor of PI occurrence in adult trauma patients (OR 13.77, 95% CI 13.25–14.31, $P < 0.001$) (Grigorian et al., 2017). On univariable analysis, the odds (OR (95% CI)) of developing a PI in patients admitted between 2007 and 2015 was 1.77 (1.73–1.81) in patients with traumatic brain injury, 2.48 (2.34–2.62) in patients with cerebrovascular accident and 13.73 (13.22–14.25) in patients with SCI (Grigorian et al., 2017). Thus, similar to patients with SCI, individuals with traumatic brain injury, stroke, neurodegenerative diseases (such as dementia, Alzheimer's disease, and Parkinson's disease) or any other neurological conditions resulting in altered level of sensation, mobility, or mental status also are at increased risk of developing a PI (Jaul, Barron, Rosenzweig, & Menczel, 2018). Furthermore, the combination of neurological impairments with associated complicating conditions such as polypharmacy, malnutrition, and anemia further increases PI susceptibility (Jaul et al., 2018). Fife et al. showed that patients who are admitted to the neurologic intensive care unit are at higher risk of developing a PI especially if they have Braden scores of $\leq$16 and are underweight (Fife et al., 2001). These results may suggest that the factors contributing to PI in patients with TSCI may also be applicable to other neurological conditions and thus shouldn't be overlooked.

Mini-dictionary of terms

Atrophy: wasting or loss of muscle tissue.
Catabolism: metabolic pathways resulting in the breakdown of complex molecules into smaller particles.
Debridement: removal of dead or unhealthy tissues in a wound.
Ischemia: decrease blood flow to tissues causing reduction in oxygen and nutrient supplies.
Maceration: prolonged exposure to moisture resulting in softening and breaking down of skin.
Necrosis: premature death of cells and tissues.
Pressure: force vector that is perpendicular to the skin.
Shear: force vector that is tangential to the tissue contact surface.
Tunneling: channels extending from the initial injury site to subcutaneous tissues.
Undermining: extension of the injury in subcutaneous tissues under the wound borders.

Key facts of pressure injuries

- A pressure injury (PI) is defined as a circumscribed injury to the skin and/or underlying tissue due to pressure, or shear combined with pressure.
- Loaded soft tissues deform, causing strains and stresses which, if sustained, may lead to tissue damage.

- Muscles are more susceptible to damage than fat and skin as they have lower tolerance to deformation.
- Patients with sensory deficits are more prone to PI due to their lack of protective responses caused by decreased awareness of tissue injury.
- Complications of PI include wound infection, cellulitis, septic arthritis, osteomyelitis, sepsis, malignant transformation (Marjolin's ulcers), surgical procedures, amputation, and death from infection.

Summary points

- Susceptibility and extent of pressure injuries (PI) depend on type, magnitude, and duration of mechanical load, the mechanical properties of the tissue, tissue and bone morphology, tissue repair capacity as well as circulation and thermal properties of tissues.
- To date, no universal safe tissue interface pressure threshold has been established.
- Following spinal cord injury (SCI), multiple structural and physiological changes occur, decreasing the body's ability to maintain skin integrity, increasing the risk of tissue breakdown and thus increasing the risk of developing PI.
- Patients are at higher risks of developing a PI during the first year post-SCI or more than 25 years post injury.
- Patients with traumatic spinal cord injury (TSCI) who develop a PI during acute hospitalization have higher complication rates, significantly longer length of stay, higher risk of recurrence, and poorer long-term functional outcome.
- Non-modifiable risk factors include more severe TSCI, poorer functional outcome, greater trauma severity and the presence of concomitant traumatic injuries, hypotension, mechanical ventilation, longer time elapsed since TSCI, previous history of PI, lower household income, unemployment, being single, lower educational levels, and presence of comorbidities.
- Modifiable risk factors include obesity, substance abuse, dysthymic symptoms, schizophrenia, personality disorders, neurocognitive changes, delirium, medication use for pain, insomnia, spasticity or stress, longer admission delay from trauma site to emergency department, longer time spent with immobilization device, longer surgical duration, longer acute care length of stay, care management in a non-SCI-specialized center, surgical delay of >24 h, medical complications, hypoalbuminemia, malnutrition, immobility in the frail, poor bed and wheelchair positioning, no access to appropriate support surfaces, poor compliance, and little or non-knowledge of PI prevention strategies.
- Although various factors have been identified as potential PI risk factors, no single component can explain PI occurrence on its own but rather a complex interaction of different factors, therefore highlighting the importance of a comprehensive management and care plan.

Chapter 6

Venous thromboembolism in spinal cord injury—Prophylaxis, diagnosis and treatment

Rodrigo Lanna de Almeida
Department of Spinal Cord Injury, Heidelberg University, Heidelberg, Germany

Abbreviations

aPTT	activated partial thromboplastin time
CSCM	Consortium for Spinal Cord Medicine
CT	computed tomography
CTPA	CT pulmonary angiography
CUS	compression ultrasonography
DVT	deep venous thrombosis
GCS	graduated compression stockings
IPCD	intermittent pneumatic compression device
IVCF	inferior vena cava filter
LMWH	low-molecular-weight heparin
MRI	magnetic resonance imaging
PE	pulmonary embolism
PESI	pulmonary embolism severity index
SCI	spinal cord injury
UH	unfractionated heparin
VKA	vitamin K antagonists
VTE	venous thromboembolism

Introduction

The classical Virchow's postulate links the occurrence of venous thromboembolism (VTE) to the presence of a disruption of the circulatory flux, a damage of the endothelial tissue, or a hypercoagulability state. Immobility and palsy are prominent risk factors for VTE and are frequently seen in clinical rules used for its diagnosis (Duffett, Castellucci, & Forgie, 2020). Individuals with a spinal cord injury (SCI) present frequently not only with impaired mobility due to the associated neurological motor deficit, but endothelial injuries and a hypercoagulability condition may also arise as a consequence of the lesion mechanism, such as trauma or neoplasms, as well as secondary complications like infections or pressure ulcers (Agarwal & Mathur, 2009; Chung et al., 2014) (Fig. 1). Thus, SCI is associated with an increased risk of venous thromboembolism in its acute phase that may extend to its chronic phase (Casas, Sánchez, Arias, & Masip, 1977; Godat, Kobayashi, Chang, & Coimbra, 2015; Todd et al., 1976).

Many advances have been made regarding risk stratification for prophylaxis and diagnostic algorithms for VTE in the general population. The proposed strategies and clinical rules however have not been validated for individuals with SCI, posing a challenge for physicians involved in the care of such patients.

Epidemiology

The reported prevalence of VTE in spinal cord injury is variable. A study by Todd et al. (1976) based on screening in asymptomatic patients with serial scintigraphy with labeled fibrinogen identified clots in 100% of the 20 studied patients.

Diagnosis and Treatment of Spinal Cord Injury. https://doi.org/10.1016/B978-0-12-822498-4.00006-3

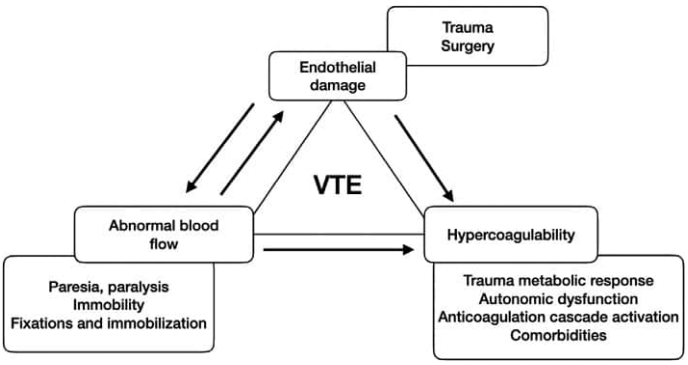

FIG. 1 Virchow's triad in spinal cord injury. This schematic representation illustrates how conditions frequently present in SCI exert a direct influence on VTE risk. *VTE*, venous thromboembolism; *SCI*, spinal cord injury. *(Based on Piran, S., & Schulman, S. (2019). Thromboprophylaxis in patients with acute spinal cord injury: A narrative review.* Semin Thromb Hemost, 45*(2), 150–156. © Georg Thieme Verlag KG.)*

Other studies that are based on clinical symptoms or less sensitive screening methods report a prevalence of 10% to 15% for deep venous thrombosis (DVT) and 5% to 10% for pulmonary embolism (PE).

The risk appears to be the highest in the first 12 weeks after the injury (Agarwal & Mathur, 2009; Casas et al., 1977), with a retrospective cohort study by Chung et al. (2014) reporting a 17 times risk increase for DVT and 3.5 times for EP within 3 months after an SCI in comparison to age- and sex-matched individuals from the general population. A study by Green (1992), however, didn't find an increased risk in the first 3 days after the lesion. It is postulated that factors like the flaccid paralysis occurring during the spinal shock phase and the need for immobilization secondary to multiple trauma may be of significance in the augmented risk during the acute stage of SCI (Fig. 2). Moreover, the dysregulation of the autonomic nervous system may lead to an imbalance of the hemostatic and fibrinolytic systems, and there is evidence of increased platelet reactivity to collagen and an imbalance in factor VIII to factor VIII-C ration (Kelly, Yoder, Tang, & Wakefield, 2010).

Published data on the incidence of VTE during the sub-acute and chronic phases of SCI are conflicting. There appears to be a reduction in this risk, approaching that of the general population, although somewhat higher. A study by Giorgi Pierfranceschi et al. (2013) reported an incidence of 34.4 VTE events per 100,000 patient-year during the first 90 days which was reduced to 0.3 events per 100,000 patient-year thereafter. Data from a systematic review indicate a PE incidence ranging from 0.5% to 6.0% and a DVT incidence between 2.0% and 8.0% in the sub-acute phase in patients under different prophylaxis strategies (Alabed, Belci, Van Middendorp, Al Halabi, & Meagher, 2016). The above-mentioned study by Chung et al. (2014) reported a cumulative risk of 1.19 times after the first year of the SCI, and studies evaluating individuals in the chronic stage demonstrated DVT incidences as low as 0.55 per 10,000 patients-day (de Almeida, Rodrigues, et al., 2019) and as high as 8% (Mackiewicz-Milewska et al., 2016) in patients admitted for rehabilitation treatment.

Without adequate treatment, the estimated mortality rates may reach 8% for DVT and 25% for PE. In studies performed with individuals with SCI, VTE may be responsible for up to 3% of all the deaths in those admitted for rehabilitation

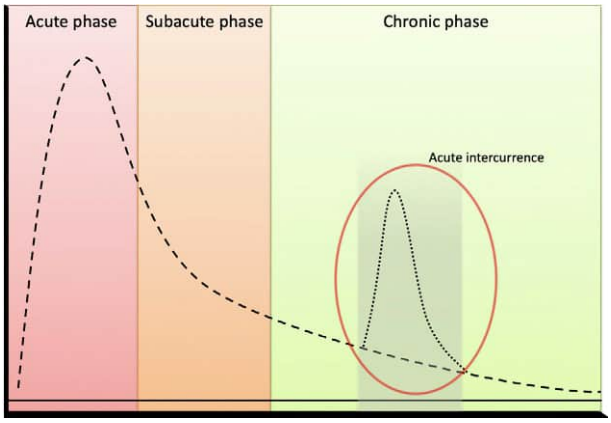

FIG. 2 Venous thromboembolism risk in spinal cord injury. VTE risk in SCI *(dashed lined)*: The risk is higher during the acute phase and decreases thereafter. Intercurrent clinical or surgical conditions may transiently elevate the risk during the chronic phase *(dotted line)*. The *solid line* represents the average VTE risk in the general population. *VTE*, venous thromboembolism; *SCI*, spinal cord injury.

(Green et al., 1994). In addition, individuals affected by VTE may present further clinical complications such as post-thrombotic syndrome, pulmonary hypertension, and recurrent VTE events (Kearon, 2003).

Screening

The rationale for screening for asymptomatic VTE is based on its high incidence in SCI, therefore being a probable and preventable cause of death during the acute phase. The identification of an asymptomatic thrombus could then lead to immediate treatment, which could hinder further complications. Proposed approaches involve performing serial lower limb duplex ultrasound (Kadyan, Clinchot, & Colachis, 2004), D-Dimer testing, or both used in combination (Kumagai et al., 2020; Masuda, Ueta, Shiba, & Iwamoto, 2015).

Even though the majority of thrombi have an origin in the lower limb circulation, up to half resolve spontaneously within 72 h, and only around a sixth of them lead to disturbance in the deep vein circulation (Kearon, 2003). Screening studies have been successful in demonstrating high sensitivity and in identifying a high number of asymptomatic VTE. As the majority of these were designed as diagnostic and not therapeutic studies, there is uncertainty about the clinical benefits of this strategy which may well lead to overdiagnosis and consequently overtreatment. Considering the bleeding risk associated with therapeutic anti-coagulation, patients might be exposed to unnecessary use of a dangerous medication.

Prophylaxis

Acute phase

Since the 1970s, uncontrolled studies proposed the use of pharmacological prophylaxis in acute SCI (Casas et al., 1977). Different approaches involving the use of unfractionated heparin (UH), vitamin K antagonists (VKA), low-molecular-weight heparin (LMWH), intermittent pneumatic compression (IPC) and electrostimulation alone or in different combinations have been tested. In comparison to mechanical prophylaxis alone, the use of pharmacological prophylaxis may lead to an absolute risk reduction of up to 15% in the incidence of VTE during the acute phase of SCI (Halim, Chhabra, Arora, & Kumar, 2014).

The major advantage of LMWH in comparison to UH is related to an average of 4% absolute reduction in the risk of bleeding (Investigators, 2003; Thumbikat, Poonnoose, Balasubrahmaniam, Ravichandran, & McClelland, 2002). Enoxaparin was the most frequently used LMWH in clinical trials involving individuals with SCI, but dosing strategies and duration of treatment were greatly varied, from 20 to 40 mg once a day, to 30 mg twice a day, from as little as 14 days up to 8 weeks or longer times based on patient mobility (Frisbie & Sasahara, 1981; Green et al., 1990; Merli et al., 1988; Merli, Crabbe, Doyle, Ditunno, & Herbision, 1992; Spivack & Aisen, 1997; Thumbikat et al., 2002), preventing these studies from being combined in a meta-analysis. Until now, we could not find any study comparing the same dosing strategy with different durations, allowing a more precise evaluation of the risk-benefit profiles of longer or shorter prophylaxis strategies.

Current guidelines agree that the pharmacological prophylaxis should be initiated as soon as possible during the acute phase, preferably within the first 72 h of the injury, taking into consideration the clinical status and, most importantly, the assessment of the risk of bleeding of the individual patient (CSCM, 2016; Fehlings et al., 2017). Recommendations regarding the duration of prophylaxis continue to be at least 8 and up to 12 weeks, which may be prolonged based on the assessment of the individual risk of VTE.

Sub-acute and chronic phase

Studies comparing prophylaxis strategies during the chronic phase of SCI are scarce. It is important to emphasize that in poor resource areas with limited access to specialized care, many individuals with SCI may only be admitted to inpatient rehabilitation already in the chronic phase. The delayed access to rehabilitation services may lead to early complications, such as structured articular mobility restrictions, pressure ulcers, recurrent infections, and obesity, which may further influence the risk of developing a VTE episode (Jorge, White, & Agarwal, 2018).

As discussed above, the risk of VTE decreases after the acute phase. The use of pharmacological prophylaxis is usually safe but encompasses nevertheless an elevation of the patient's basal risk of bleeding. Minor bleedings (hematomas at the injection site) may occur in up to 64% of patients during rehabilitation (Eichinger et al., 2018), and major bleeding events have been reported in individuals with SCI receiving prophylactic doses of LMWH (de Almeida, Gonzaga, Beraldo, & Amado, 2019). We suggest taking into consideration the individual patient risk factors, such as comorbidity, mobility, independence, concomitant use of other medications, presence of infections and near surgical procedures to decide whether or

not to initiate the pharmacological prophylaxis. Moreover, as suggested by the Consortium for Spinal Cord Medicine (CSCM) Clinical Practice Guidelines (2016), services involved in the care of individuals with SCI should have established policies regarding thromboprophylaxis which should be periodically revised and audited.

Non-pharmacological methods

Maintenance of adequate hydration, early mobilization, physical rehabilitation and promoting independence are classically described as general methods that should be applied to every patient. Intermittent pneumatic compression devices (IPCD) may be used as an alternative prophylaxis method if the risk of complications with the use of pharmacological methods is deemed to be prohibitive (CSCM, 2016). Only a small case series evaluated IPCD without a pharmacological method in individuals with SCI, reporting a 43% incidence of DVT mostly detected by screening, and only 18% of these being a proximal DVT (Chung, Lee, Kim, & Eoh, 2011). These devices are used continuously and, therefore, may interfere with the acute rehabilitation program.

A meta-analysis demonstrated that graduated compression stocking (GCS) may be effective in preventing DVT in hospitalized patients, especially those submitted to surgical and orthopedic interventions. This benefit was also seen in those receiving background thromboprophylaxis. Only two studies have used LMWH as background prophylaxis and no difference was found with the addition of GCS. Furthermore, none of the included studies compared GCS alone versus a pharmacological method (Sachdeva, Dalton, & Lees, 2018). Moreover, these devices may cause skin lesions and should not be used in conditions such as peripheral arterial disease and decompensated heart failure.

Current evidence doesn't support the prophylactic use of inferior vena cava filters (IVCF), and there may be an increased risk of VTE in individuals with SCI who underwent an IVCF implantation, even when receiving pharmacological prophylaxis (Gorman, Qadri, & Rao-Patel, 2009).

Diagnosis

The usual approach in the individual with suspected DVT or PE involves a clinical evaluation to estimate his pre-test probability based on signs, symptoms and risk factors, followed by a diagnostic strategy to rule in or rule out the diagnosis. The utility of diagnostic algorithms associated with clinical rules such as the Wells' criteria for DVT or PE, the Geneva score for PE or the PERC have been demonstrated in diverse clinical scenarios (Tritschler, Kraaijpoel, Le Gal, & Wells, 2018), but as of yet, are not validated for individuals with SCI.

Some of the clinical factors evaluated by these rules may have different significance and presentation in SCI (Table 1). Paresis or paralysis may be a major risk factor during the acute phase of an SCI, but this may not extend to the chronic phase. Benign postural lower limb edema is a frequent clinical sign in these individuals and may impair the clinical evaluation of a suspected DVT. Furthermore, the autonomic dysfunction in lesions above T6 may impair tachycardic responses (Krassioukov et al., 2012), as evaluated in some scores and pain complaints may be absent due to neurological impairment. In this scenario, it is reasonable to maintain a high level of clinical suspicion.

The test of choice for confirming or excluding the diagnosis will be based on the previously estimated pre-test probability. Moreover, the clinician should also consider how invasive the test is, the availability of the method, and trained staff for performing and interpreting the results and how high the clinical suspicion of DVT or PE is.

D-dimer

The D-dimer is a fibrin degradation product that is positive not only in VTE. Its high sensitivity—especially in quantitative and semi-quantitative tests—in general patients makes it a helpful test for ruling out the diagnosis of both DVT and PE in those with a low pre-test probability (Tritschler et al., 2018). This high sensitivity has been demonstrated in low-quality evidence studies in patients with SCI (Roussi et al., 1999) and other neurological conditions under rehabilitation treatment (Akman, Cetin, Bayramoglu, Isiklar, & Kilinc, 2004), but not as part of a diagnostic algorithm in these populations. The low specificity associated with the test is not enough to confirm the diagnosis; therefore, a positive result will lead to further testing. Despite its high sensitivity in patients presenting a high pre-test probability, a negative result won't be enough to safely rule out the diagnosis.

TABLE 1 Variables in clinical rules that may be influenced by spinal cord injury.

Wells' criteria for DVT
Asymmetric leg swelling
Whole limb edema
Tenderness along the deep venous system
Wells' criteria for PE
Heart rate above 100 bpm
Geneva score
Heart rate above 100 bpm (original score)
Heart rate above 94 bpm (revised and simplified scores)
Limb pain (revised and simplified scores)
PERC rule
Heart rate above 100 bpm
Unilateral edema

The table displays some of the risk factors present on commonly used clinical rules that may be difficult to evaluate due to neurological and autonomic dysfunction in SCI.

Lower limb ultrasonography

Compression ultrasound examination (CUS) is a highly sensitive and specific non-invasive test that may be performed as a point-of-care diagnostic strategy by trained physicians (Tritschler et al., 2018). Based on its widespread availability, non-invasiveness and ease of performance, CUS is the method of choice for the evaluation of patients with moderate or high pre-test DVT probability. This can be performed in strategies that evaluate the proximal venous circulation up to the level of the popliteal vein, requiring a follow-up examination after 1 week if negative, or a complete scan from the common femoral vein down to the deep calf veins, without a need for retesting (Wells, Ihaddadene, Reilly, & Forgie, 2018). Even though there is no specific study on the accuracy of this method in patients in SCI patients, ultrasonography seems like a reasonable method due to its availability and good performance of point-of-care examinations in comparison with expert radiologist evaluation, which may avoid delays in the diagnostic process (Fischer et al., 2019). For this same reason, lower limb sonography may be an acceptable strategy as a first examination to rule in PE in patients with a higher likelihood of this diagnosis and with clinical signs of DVT (Wells et al., 2018), but an isolated negative test is not enough to exclude it.

Lower limb venography

Venography, computerized tomography (CT), and magnetic resonance (MRI) venography are invasive methods requiring the use of contrast. Venography is considered the "gold standard" for the evaluation of the limb venous circulation. Even though a normal venography allows safe withholding of anti-coagulation, it is a limited method due to its restricted availability, costs, discomfort, and difficulties in obtaining standardized and good-quality images and proper evaluation (Bates et al., 2012). CT and MRI venography are promising methods that have demonstrated sensitivity and specificity around 95% in meta-analysis, but with high heterogeneity between studies (Abdalla et al., 2015; Thomas, Goodacre, Sampson, & van Beek, 2008). Therefore, they are not considered first-line diagnostic methods but are useful in situations where ultrasonography can't safely exclude the diagnosis, such as thrombosis in proximal or pelvic veins that are not compressible or in obese patients (Tritschler et al., 2018; Wells et al., 2018).

CT pulmonary angiography

CT pulmonary angiography (CTPA) has replaced ventilation/perfusion scintigraphy as the method of choice for the diagnosis of PE (Tritschler et al., 2018). With a high sensitivity and specificity, CTPA allows a fast and comprehensive evaluation of the pulmonary circulation and is largely available (Konstantinides et al., 2019). It also allows the evaluation of

pulmonary images which are useful for differential diagnosis. The constantly evolving technology and quality of images have led to a continual increase in sensitivity and, consequently, in the reported incidence of PE in the general population. This elevation occurred despite the current higher awareness of VTE and adherence to prophylaxis strategies and, according to studies performed in the United States, no concurrent elevation in age-adjusted mortality was observed, which suggests the occurrence of overdiagnosis (Dobler, 2019).

Small thrombus formation is not an infrequent event. One of the physiological functions of the normal lung may be to serve as a clot filter avoiding venous thrombi from reaching the systemic arterial circulation (Swan, Hitchen, Klok, & Thachil, 2019). The physician should, therefore, be aware of the potential risk involved in over-testing patients for PE, for instance, screening patients with a diagnosis of DVT for an asymptomatic PE.

Treatment

Anti-coagulation is the cornerstone of the treatment of VTE (Di Nisio, van Es, & Büller, 2016). The primary goal of the treatment is to avoid acute complications such as further embolization of deep vein originated thrombi, further impairment of pulmonary function or pulmonary circulation with consequent cardiovascular instability (Burgazli et al., 2013). Adequate quality therapeutic anti-coagulation may also improve late outcomes, such as post-thrombotic syndrome (Ten Cate-Hoek, 2018). Affected individuals should receive treatment to achieve rapid anti-coagulation with posterior long-term maintenance with adequate time in therapeutic range (TTR). A summary of commonly used medications is presented in Table 2.

Initial management

Initial treatment aims to quickly achieve effective anti-coagulation, which can be done both with parenteral and oral agents. Before initiating any anti-coagulant, the risk of bleeding as well as hemodynamic conditions of the individual should be assessed.

TABLE 2 Commonly used anti-coagulant agents.

	Class	Dosing	Effect reversal
Parenteral agents			
Heparin	UH	Bolus: 80 μg/kg IV Maintenance: 18 μg/kg h IV Adjust dose according to aPTT	Protamine
Enoxaparin	LMWH	1 mg/kg 12/12 h SC	May benefit from protamine use
Fondaparinux	Pentasaccharide	<50 kg: 5 mg SC daily 50–100 kg: 7.5 mg SC daily >100 kg: 10 mg SC daily	May benefit from andexanet alfa (off label) or activated prothrombin complex concentrate
Oral agents			
Apixaban	Factor Xa inhibitor	10 mg twice daily for 7 days followed by 5 mg twice daily	– Andexanet alfa (off label for edoxaban reversal)
Rivaroxaban		15 mg twice daily for 21 days followed by 20 mg daily	
Edoxaban		60 mg once daily	
Dabigatran	Direct thrombin inhibitor	150 mg twice daily	– Idarucizumab
Warfarin	Vitamin K antagonist	2–10 mg once daily for 2 days. Adjust according to INR	– Vitamin K (intravenous preparations) – Four-factor prothrombin complex concentrate – Fresh-frozen plasma

Characteristics of some of the anti-coagulants commonly used in clinical practice. Detailed information about anti-coagulation reversal is beyond the scope of this chapter. We recommend referring to the manufacturer's information for detailed dosing and administration orientation. aPTT, activated partial thromboplastin time; *INR*, international normatized ratio; *IV*, intravenous; *LMWH*, low-molecular-weight heparin; *SC*, subcutaneous; *UH*, unfractionated heparin.

There's no validated score for bleeding risk estimation in individuals with SCI receiving anti-coagulant treatment; therefore, a thorough assessment of comorbidities, previous traumas, and surgeries is mandatory (Table 3). For hemodynamically unstable individuals and those who may need urgent or emergent surgery or that may benefit from thrombolytic therapy, the use of short-acting and easily reversible anti-coagulants should be preferred.

Unfractionated heparin (UH) is a polysaccharide solution with an average molecular weight of 15,000 Da, most of them with a low binding affinity with the anti-thrombin molecule (Onishi, St Ange, Dordick, & Linhardt, 2016). It is administered intravenously initially as a bolus followed by a continuous infusion with monitoring of the activated partial thromboplastin time (aPTT) and infusion adjustments every 4 to 6 h (Hull et al., 1992; Raschke, Reilly, Guidry, Fontana, & Srinivas, 1993). It is the therapy of choice for individuals with chronic renal disease as well as for those in whom the need for rapid interruption and reversal of the anti-coagulant effect is a concern, which can be achieved with the use of the antidote protamine (Di Nisio et al., 2016).

Low-molecular-weight heparin (LMWH) is obtained through the enzymatic breakdown of heparin polysaccharides, potentiating its affinity to the anti-thrombin molecule and, consequently, its ability to inhibit factor Xa (Onishi et al., 2016). In comparison to UH, LMWH treatment is associated with a lower occurrence of thrombotic complications and major hemorrhages (Robertson & Jones, 2017). Other advantages are facilitated fixed weight-based dosing, a longer half-life facilitating dose scheduling, and a lower risk of heparin-induced thrombocytopenia (Weitz, 1997).

Pentasaccharides, such as Fondaparinux, are ultralow-molecular-weight heparins with a high binding affinity to anti-thrombin that strongly and indirectly inhibits factor Xa. Its major advantage is the facilitated dosing scheme based on a weight range. According to a meta-analysis, pentasaccharides may be as effective and safe when compared to standard treatments (Brandao, Junqueira, Rollo, & Sobreira, 2017). Studies appraised in this meta-analysis used different types of comparison treatments including UH or LMWH followed by oral vitamin K antagonists (VKA) which may have influenced the final results.

Novel oral anti-coagulants (NOACs) were developed aiming to eliminate the difficulties encountered when managing individuals using VKAs. They have a rapid onset, predictable therapeutic effect, a fixed-dose schedule, do not require laboratory monitoring nor dose adjustments, and appear to be safer regarding bleeding risk compared to VKAs (Oliphant, Jacobs, Kabra, & Das, 2013). Their action can be directed to thrombin (Dabigatran) or factor Xa inhibition (Apixaban, Edoxaban, and Rivaroxaban).

Only Rivaroxaban and Apixaban were evaluated as initial and long-term therapy without previous administration of LMWH. Rivaroxaban was evaluated both in a DVT (Bauersachs et al., 2010) and on a PE trial (Büller et al., 2012), each one with more than 3000 individuals, whereas only a third of the 5400 studied individuals on the Apixaban trial had PE (Agnelli et al., 2013). Overall, they were shown to be non-inferior to standard treatment, with a trend to less bleeding events (Gómez-Outes, Terleira-Fernández, Lecumberri, Suárez-Gea, & Vargas-Castrillón, 2014), however, to this moment, they are still more expensive in comparison to VKAs.

Anti-coagulation after initial management

After initial management, anti-coagulant treatment is maintained for 3 months or longer depending on the clinical presentation (whether DVT or PE), the individual ability to comply with the treatment, risk of recurrence, bleeding risk, costs, and clinical intercurrences. Oral agents are the preferred strategy, but LMWH and pentasaccharides are reasonable alternatives.

Vitamin K antagonists are the most frequently used oral anti-coagulant agents in the outpatient setting. Despite the necessity of constant laboratory monitoring and their narrow therapeutic range (Oliphant et al., 2013), they present lowest monthly cost considering the medication alone, are widely available and clinicians have been managing individuals using these agents for more than 60 years (Thean & Alberghini, 2016). The quality of the anti-coagulation is measured by the time in therapeutic range (TTR). A TTR below 65% is associated with a higher risk of both thromboembolic and bleeding events. Strategies to improve the TTR include management in anti-coagulation clinics, use of decision support systems, and point-of-care or self-testing (Schein et al., 2016). Adequate support through anti-coagulation clinics was shown to be effective even in poor resource and low level of formal education settings (Costa, Ferreira, Valacio, & Vieira Moreira, 2011).

NOACs are also used in long-term coagulation. Besides the above mentioned Apixaban and Rivaroxaban, the factor Xa inhibitor Edoxaban and the direct thrombin inhibitor Dabigatran have also been tested for the chronic anti-coagulation in individuals with VTE with results lying within the non-inferiority margin for VTE recurrence. There's no study with a direct comparison between these agents. A network meta-analysis pooling studies of the four agents failed to identify any specific benefit regarding VTE recurrence or VTE-related death, but there was a trend toward a reduction of clinically relevant bleeding with apixaban and dabigatran (Cohen et al., 2015). Patients using NOACs probably have a better TTR; nevertheless, the clinician should be aware that these medications are not indicated for patients with reduced renal function

TABLE 3 Risk factors for bleeding with anti-coagulant therapy.

Risk factors[a]			
Age > 65 years			
Age > 75 years			
Previous bleeding			
Cancer			
Metastatic cancer			
Renal failure			
Liver failure			
Thrombocytopenia			
Previous stroke			
Diabetes			
Anemia			
Antiplatelet therapy			
Poor anti-coagulant control			
Comorbidity and reduced functional capacity			
Recent surgery[b]			
Frequent falls			
Alcohol abuse			
	Estimated absolute risk of major bleeding (%)		
Categorization of risk of bleeding[c]	**Low risk (0 risk factors)[d]**	**Moderate risk (1 risk factor)[d]**	**High risk (≥2 risk factors)[d]**
Anti-coagulation 0 to 3 months			
Baseline risk (%)	0.6	1.2	4.8
Increased risk (%)	1	2	8
Total risk (%)	1.6[e]	3.2	12.8[f]
Anti-coagulation after first 3 months[g]			
Baseline risk (%/year)	0.3[h]	0.6	≥ 2.5
Increased risk (%/year)	0.5	1	≥ 4
Total risk (%/year)	0.8[i]	1.6[i]	≥ 6.5

[a] *The increase in bleeding associated with a risk factor will vary with (1) severity of the risk factor, (2) temporal relationships, and (3) how effectively a previous cause of bleeding was corrected.*
[b] *Important for parenteral anti-coagulation (e.g., first 10 days), but less important for long-term or extended anti-coagulation.*
[c] *Although there is evidence that risk of bleeding increases with the prevalence of risk factors, this categorization scheme has not been validated. Furthermore, a single risk factor, when severe, will result in a high risk of bleeding (e.g., major surgery within the past 2 days, severe thrombocytopenia).*
[d] *Compared with low-risk patients, moderate-risk patients are assumed to have a twofold risk and high-risk patients an eightfold risk of major bleeding.*
[e] *The 1.6% corresponds to the average of major bleeding with initial UFH or LMWH therapy followed by VKA therapy. We estimated baseline risk by assuming a 2.6 relative risk of major bleeding with anti-coagulation (refer to footnote g).*
[f] *Consistent with frequency of major bleeding observed in previous studies.*
[g] *It's estimated that anti-coagulation is associated with a 2.6-fold increase in major bleeding based on comparison of extended anti-coagulation with no extended anti-coagulation. The relative risk of major bleeding during the first 3 months of therapy may be greater than during extended VKA therapy because (1) the intensity of anti-coagulation with initial parenteral therapy may be greater than with VKA therapy; (2) anti-coagulant control will be less stable during the first 3 months; and (3) predispositions to anti-coagulant-induced bleeding may be uncovered during the first 3 months of therapy. However, studies of patients with acute coronary syndromes do not suggest a ≥ 2.6 relative risk of major bleeding with parenteral anti-coagulation (e.g., UFH or LMWH) compared with control.*
[h] *Estimated baseline risk of major bleeding for low-risk patients (and adjusted up for moderate- and high-risk groups as per footnote d).*
[i] *Consistent with frequency of major bleeding during prospective studies of extended anti-coagulation for VTE.*

and are more expensive than VKAs, and specific antidotes for anti-coagulation reversal are not widely available and are high-cost agents.

Special situations

Due to its ease of administration, LMWH may also be used for long term anti-coagulation in special situations, being for a long time the agent of choice in individuals with concomitant active neoplastic disease, as this strategy has demonstrated a lower VTE recurrence rate in clinical trials (Kahale et al., 2018). Recent studies have compared the agents Apixaban, Edoxaban and Rivaroxaban to LMWH for long term management of cancer associated VTE in a non-inferiority design. These agents were non-inferior to LMWH for the prevention of recurrent VTE, but there are concerns about a possible increased risk of bleeding especially in upper gastrointestinal cancer, acute leukemia, and primary or metastatic central nervous system tumors. Furthermore, NOACs may interact with different chemotherapeutic agents, therefore demanding a thorough evaluation of patients' bleeding risk, therapeutic plan as well as patients' preferences and prognosis (Duffett et al., 2020).

LMWH is also the preferred agent for pregnant women or women exposed to the possibility of pregnancy, due to a possible risk of fetal complications with other agents (Kearon et al., 2016).

ICVF may be an alternative for patients with VTE, whose clinical situation doesn't permit anti-coagulation, but there is no current evidence of benefit in the association of IVCF with anti-coagulation (Mismetti et al., 2015).

Outpatient management

The management of VTE was facilitated after the advent of the NOACs due to their ease of administration and lack of necessity for laboratory monitoring. Moreover, Apixaban and Rivaroxaban are also approved for the acute management of DVT and PE, which could permit the prescription of oral medication in the emergency department followed by discharge and outpatient management. This strategy may be associated with reduced costs, less exposure to nosocomial resistant microorganisms, and reduced use of available beds. On the other hand, there is the risk of delayed treatment of complications associated with progression of the thrombotic event or bleeding.

Outpatient treatment is an acceptable strategy both for DVT and PE in those patients whose embolic and bleeding risks are deemed to be low and have access to a medical center for surveillance or treatment of complications. The pulmonary embolism severity index (PESI) and the Hestia criteria (Table 4) have been used to assess disease severity in PE (Wolf et al., 2018), but these were not validated in individuals with SCI. Moreover, both the SCI associated autonomic dysfunction, risk of autonomic dysreflexia, reduced respiratory reserve in patients with higher lesions, and sensory impairment may influence the patient's risk and should be taken into consideration. A shared decision-making strategy where individuals are informed in detail about possible risks and benefits should be used.

Duration of anti-coagulation

To this moment no clinical trial was conducted specifically with individuals with SCI to determine the optimal duration of anti-coagulation. Guidelines directed at the general population agree on a treatment duration of at least 3 months for DVT, distal isolated DVT, and PE (Kearon et al., 2016; Konstantinides et al., 2019; Mazzolai et al., 2018). The decision of extending this period should be made on an individual basis, considering the risk of recurrence, especially the presence or resolution of provoking factors, and the risk of bleeding.

VTE occurring during the acute phase of SCI (i.e., during the period of higher thromboembolic risk) may be considered a provoked episode. During the chronic phase of SCI, individuals may be exposed in different periods to risk factors for VTE, such as bed rest due to fractures, pressure ulcers, or surgery. However, defining the most adequate treatment in otherwise healthy and active individuals with chronic SCI remains challenging.

Proposed strategies for this decision involving D-Dimer testing, evaluation of residual thrombosis (Carrier et al., 2011), clinical rules such as the HERDOO2, the DASH score, and the Vienna prediction model have demonstrated diverging results, lack external validation (Di Nisio et al., 2016; Tritschler et al., 2018) and individuals with SCI are underrepresented in the derivation and internal validations cohorts. Testing for inherited or acquired thrombophilia is not recommended after the first episode of provoked or unprovoked VTE and even a known thrombophilia may not necessarily grant an indication of long-term anti-coagulation after a VTE related to a strong provoking factor (Duffett et al., 2020).

TABLE 4 Pulmonary embolism severity index and Hestia rule.

Criteria	Points assigned
Pulmonary embolism severity index (PESI)	
Age in years (per year)	1
Male sex	10
History of cancer	30
History of heart failure	10
History of chronic lung disease	10
Systolic blood pressure < 100 mmHg	30
Pulse rate ≥ 110 per minute	20
Arterial oxygen saturation < 90%	20
Respiratory rate ≥ 30 per minute	20
Temperature < 36°C	20
Altered mental status	60
Score interpretation	
Class I, very low risk	<65
Class II, low risk	66–85
Class III, intermediate risk	86–105
Class IV, high risk	106–125
Class V, very high risk	>125
Hestia rule	
Is the patient hemodynamically unstable?[a]	
Is thrombolysis or embolectomy necessary?	
Active bleeding or high risk of bleeding?[b]	
>24 h of oxygen supply to maintain oxygen saturation > 90%?	
Is pulmonary embolism diagnosed during anti-coagulant treatment?	
Severe pain needing intravenous pain medication for >24 h?	
Medical or social reason for treatment in the hospital for >24 h (infection, malignancy, no support system)?	
Does the patient have a creatinine clearance of <30 mL/min?[c]	
Does the patient have severe liver impairment?[d]	
Is the patient pregnant?	
Does the patient have a documented history of heparin induced thrombocytopenia?	

HESTIA interpretation: If the answer to one of the questions is yes, in-hospital treatment is recommended. If the answer to all the questions is no, home treatment is recommended.
[a]*Including but not restricted to the following criteria: systolic blood pressure < 100 mmHg with heart rate > 100 beats/min; condition requiring admission to an intensive care unit.*
[b]*Gastrointestinal bleeding in the preceding 14 days, recent stroke (<4 weeks ago), recent operation (<2 weeks ago), bleeding disorder or thrombocytopenia (platelet count < 75.109/L), uncontrolled hypertension (systolic blood pressure > 180 mmHg or diastolic blood pressure > 110 mmHg).*
[c]*According to the Cockroft-Gault formula.*
[d]*Left to the discretion of the physician.*
Based on Roy, P. M., Moumneh, T., Penaloza, A., & Sanchez, O. (2017). Outpatient management of pulmonary embolism. *Thrombosis Research, 155,* 92–100.

Conclusion

VTE is a frequent complication of SCI and adequate prevention and management is a challenge for the multi-disciplinary team involved in the care of these individuals. There is a current lack of SCI-directed evidence, which is an exciting starting point for future research. There are remaining questions that need to be addressed regarding the optimal duration of pharmacological prophylaxis and anti-coagulation treatment, especially in individuals with chronic SCI.

Applications to other areas of neuroscience

In this chapter, we review the clinical management of venous thromboembolism including its epidemiology, prophylaxis, diagnosis, and management. Venous thromboembolism is a possible complication in individuals presenting with paresis or plegia, especially those with an acute presentation, such as acute stroke, brachial or lumbar plexus lesion.

The occurrences of deep venous thrombosis or pulmonary embolism are factors that may delay and interfere with the rehabilitation process and expose patients to a treatment that is not risk-free (Akman et al., 2004). Institution of adequate prophylaxis, defining precisely the ideal moment to initiate or interrupt pharmacological prophylaxis, is important in order to prevent not only venous thromboembolism but also iatrogenic bleeding. These are challenges that are also present when dealing with individuals with Guillain-Barré syndrome, acute ischemic or hemorrhagic stroke, and traumatic brain injury.

As medical knowledge is constantly evolving with the addition of new evidence from clinical research, the concepts presented here aim to help the healthcare provider in the process of clinical reasoning and decision making.

Mini-dictionary of terms

Acute phase: Comprises the first 12 weeks after a spinal cord injury.
Chronic phase: Spinal cord injury of 6 months or more.
Novel oral anti-coagulants: Also known as non-vitamin K antagonist oral anti-coagulants or NOACs are oral anti-coagulants that directly inhibit factor Xa or thrombin. They do not require laboratory monitoring.
Clinical rules or clinical prediction rules: Scores derived from risk factors, clinical characteristics and laboratory values that focus on probability estimation, in this chapter the probability of a venous thromboembolism diagnosis or recurrence.
Pre-test probability: Refers to the estimated probability of having a diagnosis before a test result is available.
Post-thrombotic syndrome: A consequence of valvular dysfunction on the venous circulation after a thrombotic event. Symptoms include limb edema, pain, skin pigmentation, and in severe grades venous ulcers.

Key facts of venous thromboembolism in spinal cord injury

- VTE is a frequent complication of SCI, especially during the acute phase.
- It was one of the major causes of death during acute treatment.
- VTE Prophylaxis has been researched since the 1970s, and most VTE studies in individuals with SCI are directed at prophylaxis strategies.
- Neurological deficits and autonomic dysfunction may interfere with the diagnostic process.
- Both VTE-associated and anti-coagulant-associated bleeding may cause delays in rehabilitation.

Summary points

- Pharmacological prophylaxis with LMWH should be used at least in the first 3 months after the SCI.
- The decision about pharmacological prophylaxis in patients with chronic SCI should be made on an individual basis.
- A high level of suspicion for the diagnosis should be maintained, but screening methods for VTE are not recommended.
- Classical clinical rules for the diagnosis of DVT and PE are not validated for individuals with SCI.
- Anticoagulation with parenteral or oral agents is the cornerstone of the treatment and should be used for at least 3 months.
- Prolongation of treatment should be made on an individual basis.
- Bleeding may occur even on prophylactic doses of anti-coagulants and sensorial deficit may delay the diagnosis.

Introduction

In 2017, approximately 22 million people around the world were living with a spinal cord injury (SCI), a rate increase of 14.21% in the last 10 years (GBD 2016 Traumatic Brain Injury and Spinal Cord Injury Collaborators, 2019). The better access to medical care resources such as emergency medical services and rehabilitation departments led to longer survival for this population (Frontera & Mollett, 2017). Henceforth, many consequences were related to SCI such as neurogenic bladder, neurogenic bowel, neuropathic pain, spasticity, and osteoporosis (Craven, Robertson, Delparte, Ashe, & Janice, 2008; Frontera and Mollett, 2017).

Osteoporosis affects the health of individuals with SCI because it increases the risk of fragility fractures with consequences related to fractures such as ulcers, immobility, depression and even death (Carbone et al., 2013; Jiang, Dai, & Jiang, 2006; Morse et al., 2009). Osteoporosis after SCI is defined as an excessive bone resorption after SCI and bone fragility fractures are defined as fractures caused by a trauma that would be insufficient for a normal bone to fracture (Craven et al., 2008; Zleik et al., 2019) or by minimally loaded situations (McPherson et al., 2014; Shields et al., 2005).

The impact of fractures on the lives of individuals with SCI suggests that most patients will be hospitalized after the fracture and undergone to surgery, and complications as worse performance in activities of daily living and ambulation after the fracture are mostly described. These issues mean increased disability and costs for the health system (Carbone et al., 2013).

Diagnosis and Treatment of Spinal Cord Injury. https://doi.org/10.1016/B978-0-12-822498-4.00007-5

Special attention should be paid to the prevention of fractures, and appropriate treatments should be instigated to prevent excessive bone loss and futher investigations should be performed. Most of the physicians are not educated to measure risk factors for bone fragility fractures. Dual-energy X-ray absorptiometry (DEXA) should be performed in patients with SCI, likely before the occurrence of fractures. Bone remodeling markers could give us a clue of the resorption rate and treatments to prevent further loss should be consider.

Physiopathology

Bone demineralization after SCI occurs in a rate loss of approximately 4% per month in the first year (Battaglino, Lazzari, Garshick, & Morse, 2012; Bauman, Spungen, Morrison, Zhang, & Schwartz, 2005; Bauman, Wecht, et al., 2005), primarily in the knees. Demineralization begins in the early days, peaks around the 10th to 16th weeks and stabilizes around the 16th to 24th months (Battaglino et al., 2012; Bauman, Spungen, et al., 2005; Bauman, Wecht, et al., 2005). Recent studies suggest that the bone loss extends 3 to 8 years after SCI (Haider, Lobos, Simonian, Schnitzer, & Edwards, 2018). Previous studies demonstrated bone demineralization greater than 20% in the hip, 37% to 52% in the distal femur and 36% to 70% in proximal tibia after 1 to 3 years after SCI (Garland, Adkins, & Stewart, 2005; Haider et al., 2018; Troy & Morse, 2015).

Bone loss associated with SCI is related to immobility and metabolic changes (Bauman & Spungen, 2000; McPherson et al., 2014; Uebelhart, Demiaux-Domenech, Roth, & Chantraine, 1995). Individuals with SCI exhibit primarily hypercalcemia, hypercalciuria, hyperparathyroidism, decreased levels of osteocalcin, and higher levels of sclerotin. The loss of bone mineral density is 2 to 4 times greater than the loss that occurs in an immobilized individual without SCI (Uebelhart et al., 1995).

Other related factors may contribute to this bone loss, such as vitamin D deficiency and the use of methylprednisolone, anti-convulsant drugs, and psychotropic substances. Previous studies discovered that 14% to 32% of individuals with SCI were deficient in vitamin D (Bauman, Zhong, & Schwartz, 1995; Koutrakis et al., 2019). Even in tropical countries, vitamin D deficiency is a common health problem (Champs, Maia, Oliveira, de Melo, & Soares, 2020).

Fractures

The consequence of osteoporosis in individuals with SCI is fracture due to bone fragility. It usually occurs in transfers and activities with minimal or no trauma, such as low-speed falls, torsional stress (Akhigbe et al., 2015; Bethel et al., 2016). Studies (Akhigbe et al., 2015; Bethel et al., 2016; Champs et al., 2020) detected a specific time between SCI and fracture was 9 to 10 years, average age of first fracture for women 50+ and for men 40 + years-old (Champs et al., 2020). Fractures may occur in 25% to 46% of these individuals over their lifetimes (Bethel et al., 2016; Craven, Robertson, McGillivray, & Adachi, 2009; Morse et al., 2009). Fractures are primarily related to torsional forces during transfer, passive mobilization, compressive forces, and falls (Akhigbe et al., 2015; Bethel et al., 2016; Champs et al., 2020). It seems the most frequent fracture cause is due to falls from a wheelchair or even their own height while walking or standing (Champs et al., 2020). This result is not surprising because falls are a common health problem in individuals with SCI, and the prevention of falls should be a priority. Another study found transfer as the main cause of fracture (Akhigbe et al., 2015).

The risk of fracture after SCI is different from the risk of osteoporosis (Abderhalden et al., 2017; Cirnigliaro et al., 2017), individuals with tetraplegia have more osteoporosis than those with paraplegia, however, individuals with paraplegia have a higher frequency of fractures due to exposure to falls (Champs et al., 2020; Craven et al., 2009; Morse et al., 2009). Most places of fractures are in the tibia and/or distal fibula, distal femur, or hip/proximal femur and proximal tibia (Akhigbe et al., 2015; Bethel et al., 2016; Morse et al., 2009). It seems hip/proximal femur and distal tibia/fibula are as common as the distal femur (Champs et al., 2020). However, individuals who are ambulatory and wheelchair dependent may have different areas of fractures. Ambulatory individuals fracture more often the distal tibia/fibula, and wheelchair-bound patients fractured the distal and proximal femur (Champs et al., 2020). A second (15%) and third (2%) fracture are experienced by patients (Champs et al., 2020).

The impact of fractures on the lives of people with SCI suggests that most of the patients are hospitalized after the fracture, and some had complications. Almost one-third of the participants reported worse performance in activities of daily living and ambulation after the fracture had healed. Individuals with osteoporosis-related fractures after SCI had several complications. Most individuals were hospitalized, and half of them underwent surgery (Champs et al., 2020). These issues mean increased disability and costs for the health system.

Risk factors

Previous studies showed risk factors (Bethel et al., 2016; Garland et al., 2005; Morse et al., 2009) and the following ones were described associated with increased fracture criteria: AIS (ASIA Impairment Scale) A or B; age 40+ years old; SCI longer than 3 years; age at SCI of 16 years or less; three servings of coffee per day; smoking; women; family history of osteoporotic fractures; low bone mineral density; low weight Bone Mass Index (BMI) <19 kg/cm^2; alcohol intake greater than 30 g/day; paraplegia, and the use of corticosteroids (Craven et al., 2008, 2009). Studies by Craven developed protocols conducive to treatment based on these risk factors. Other aspects related to fractures are 25 hydroxyvitamin D [25(OH)D] levels less than 20 ng/mL (Koutrakis et al., 2019).

Diagnosis

Laboratory

Bone formation markers are useful in the management of SCI patients. Procollagen type I N-propeptide reflects osteoblastic activity, bone-specific alkaline phosphatase, which is a bone formation marker, is elevated on the first year after injury. Osteocalcin, another bone remodeling marker is reduced in the first year others (Bauman and Spungen, 2000; Uebelhart et al., 1995).

Bone resorption markers such as deoxypyridinoline, pyridinoline, sclerostin, and type I collagen C-telopeptide (CTX-I) can be used. CTX-I is increased in the second week after SCI and peaks between 2 and 4 months, and its levels can remain increased for up to 5 years (Bauman and Spungen, 2000; Uebelhart et al., 1995).

The immobilization resulting from acute SCI stimulates osteoclastic bone resorption and calcium homeostasis markers as parathyroid hormone (PTH) is reduced in the first year after injury, urinary calcium is elevated, serum calcium is increased, while ionized calcium is generally normal. These alterations peak from the 3rd to the 10rd month after SCI (Bauman and Spungen, 2000; Uebelhart et al., 1995).

Dual-energy X-ray absorptiometry

Dual-energy X-ray absorptiometry (DEXA) for patients with SCI is a confirmatory test to predict the future risk of fracture and also serves for ongoing monitoring of bone health and to access bone loss (McPherson et al., 2014) by the bone mineral density (BMD) measurements. It is precise and safe (Shields et al., 2005) since there were strong associations among different observers and it emits a very low level of radiation (0.1 mSV), that is, 1/10–1/30 less radiation than a chest X-ray. DEXA calculates the measurement of bone mineral density in g/cm^2 and protocols for calculating bone mineral density for patients with SCI already exist. Some studies suggested that low BMD in the hip predicted fracture in individuals with SCI (Abderhalden et al., 2017) and other authors suggested that DEXA measurement of the distal femur and proximal tibia, with specific protocols for the evaluation of these sites (Cirnigliaro et al., 2017; Garland et al., 2005; Morse et al., 2009) and for knee fracture thresholds of 0.78 g/cm^2 which a fracture may start to occur and fracture breakpoint of 0.49 g/cm^2 (Garland et al., 2005; Fig. 1).

The measurement of BMD of the knees is extremely important for monitoring bone loss, as the hip and spine do not show the highest losses of BMD after SCI and because osteoporosis is most severe below the level of the injury (Morse, Biering-Soerensen, et al., 2019; Morse, Troy, et al., 2019). It can be even more useful in those patients where assessing the spine and hip is not possible, such as cases with spine surgeries or hip heterotopic ossifications. The limitations for measuring BMD in the knees are fractures and orthopedic surgeries. In cases of flexion deformities, the assessment of bone mineral density can be performed in the lateral scans (Fig. 2).

Quantitative computed tomography

Quantitative computed tomography (pQCT) is also a safe method and evaluates density, volume and geometry, differentiates cortical bone and trabecular bone, but it is difficult to establish prediction, and have plus radiation, and aBMD <114 mg/cm^3 in the femur and aBMD <72 mg/cm^3 in the tibia are described as fracture thresholds (Garland et al., 2005; Liu et al., 2000).

Treatment

It is still under debate the best way to prevent fragility fractures after SCI (Morse, Biering-Soerensen, et al., 2019; Morse, Troy, et al., 2019). A diet rich in fruits and vegetables, daily doses of calcium of 1000 to 1200 mg vitamin D,

FIG. 1 Dual-energy X-ray absorptiometry (DEXA) scan image of the knee. The boxes delineate the regions of the affected area scanned at the distal femur (*blue box* 1: distal femoral epiphysis and *blue box* 2: distal femoral metaphysis) and the proximal tibial (*blue box* 3: proximal tibial epiphysis).

FIG. 2 Digital X rays scans of the spine and the hip. Spine surgeries and heterotopic ossifications in the hip artificially increase bone mineral density.

200 to 1000 iU/day aiming a serum level of 30 ng/dL, physical exercises, stop smoking and drinking alcoholic beverages and avoid over doses of coffee are contributive recommendations (Bauman et al., 2015; Koutrakis et al., 2019; Morse, Biering-Soerensen, et al., 2019; Morse, Troy, et al., 2019).

Pharmacologic therapy

Studies showed the efficacy of bisphosphonates in daily doses of alendronate 10 mg (orally) and calcium 500 mg to decrease bone turnover in people with SCI (Zehnder et al., 2004). Bisphosphonates were more effective if 25-OH > 33 ng/mL and vitamin D deficiency should be investigated because of osteomalacia risk (Morse, Biering-Soerensen, et al., 2019; Morse, Troy, et al., 2019). However, it is a medication with around 50% adherence despite being generally well-tolerated (Morse, Biering-Soerensen, et al., 2019; Morse, Troy, et al., 2019). The association of calcium 500 mg, alendronate, 70 mg weekly and vitamin D 400 U starting 10 days after SCI and use for twelve months to 24 months prevented the decrease of BMD in the distal tibial epiphysis in patients with SCI (Gilchrist et al., 2007; Zehnder et al., 2004). In contrast, the isolated use of 500 mg of calcium daily for the same period didn't prevent it (Gilchrist et al., 2007).

Pamidronate 60 mg usage, intravenously 4 times a year associated with dietary calcium (700 mg/day) and vitamin D, didn't prevent bone loss in the long term, in patients with spinal cord injury with complete motor injury (Bauman, Spungen, et al., 2005; Bauman, Wecht, et al., 2005). Zoledronic acid administered once a year, intravenously, showed a significant reduction in bone loss of lumbar spine, hip and trochanter with some side effects as myalgia, fever and nasal congestion (Shapiro et al., 2007). Another study described zoledronic acid administration failed to prevent bone loss at the knee in persons with acute spinal cord injury (Bauman et al., 2015).

Many complications are associated with bisphosphonates as hypocalcemia, gastrointestinal effects, osteomalacia, osteonecrosis of the jaw (1/10,000 patients) after more than 4 years of use, atrial fibrillation, hepatotoxicity, teratogenicity for women of childbearing age and it cannot be used in chronic renal failure.

Vitamin D is also effective (Bauman, Spungen, et al., 2005; Bauman, Wecht, et al., 2005). Vitamin D treatment determined significant reduction of urinary bone resorption markers despite neutral effects on bone formation markers (Bauman, Spungen, et al., 2005; Bauman, Wecht, et al., 2005).

Teriparatide reduced the risk of vertebral fractures at a dose of 20 μg daily, subcutaneously, when associated with robotic treatment. Teriparatide alone, did not improve BMD either on the spine or on the hip for patients with SCI (Chain, Koury, & Bezerra, 2012).

Denosumab inhibits osteoclast formation, prevents bone resorption, and reduces risk of spine fractures. A study by Gifre et al. (2016) treated 14 patients with SCI with denosumab, calcium, and vitamin D with improvement of bone mineral density in 12 months. Despite that, there are still poor evidence for people with SCI.

There is no consensus on the follow-up after staring pharmacologic therapy. It is recommended to repeat DEXA after 1 to 2 years after start of treatment (Morse, 2019).

Treatment with bisphosphonate has been done for 4 to 5 years and should be consider drug holiday after 3 to 5 years of use, because of its prolonged effect (Morse, Biering-Soerensen, et al., 2019; Morse, Troy, et al., 2019).

Rehabilitation/non-pharmacological therapy

One of the possible causes of osteoporosis after SCI is the inability to perform weight bearing activities and loss of the strengthening effects of bone stress related to muscular contraction and gravity. In this way, rehabilitation is an option for osteoporosis prevention and treatment after SCI focus on stimulation muscle contraction and weight bearing in order to stimulate the mechanical stress, to which bone is exposed to daily activities among healthy people (Craven et al., 2008; Dolbow et al., 2011).

The mechanostat theory, based on Wolff's law, states that mechanical loading influences bone structure by changing its mass (amount of bone) and architecture (its arrangement) to provide a structure that resists to habitual loads. There are strains within bone that are kept within certain limits by adding and removing bone tissue that could promote bone strengthening, depending on the applied forces. The paralysis secondary SCI causes a decrease in the mechanical load and results in bone tissue loss (Cirnigliaro et al., 2017; Dolbow et al., 2011).

Standing and walking

Supported standing with standing frames, tilt tables, long leg braces, wheelchair standing have long been used as a treatment for reducing and or delaying osteoporosis after SCI. It is traditionally incorporated in rehabilitation programs, even without proof of its effectiveness (Goktepe, Tugcu, Yilmaz, Alaca, & Gunduz, 2008).

There are three good quality studies that evaluate the influence of weight bearing activities in the acute phase of SCI, with controversial results (Alekna, Tamulaitiene, Sinevicius, & Juocevicius, 2008). It was observed that an early mobilized subject showed no or insignificant loss of trabecular bone when compared with non-interventional groups (De Bruin et al., 1999). In the same other way, two studies has found that patients who performed daily standing or walking exercises for more than 1 h, 5 times per week had significantly higher BMD in the lower extremities after 2 years, in comparison to those who did not perform standing movements (Alekna et al., 2008).

For the chronic phase, the results seemed more uniform, with very little evidence of any gain in BMD when the first year after injury had passed (Biering-Sørensen, Hansen, & Lee, 2009). Goktepe et al. found no significant effect on BMD in chronic patients after daily standing for less or more than 1 h for a period of 4 years (Goktepe et al., 2008). In the same way, a study by Kunkel et al. (1993) did not detect changes in fracture risk at femoral neck after standing in a frame program for 45 min twice a day for 5 months. Dudley-Javoroski et al. compared the effect of bone compressive loads using 0% body weight (no standing), 40% body weight (passive standing—"low dose"), and 150% body weight (quadriceps stimulation in supported stance—"high dose"). After a 3 year training protocol, 3 times a week, the high dos group had an attenuated BMD decline when compared to passive standing or no standing individuals. There were no differences between low-dose and no standing group, suggesting that BMD for participants doing passive stance is the same as those who performed no standing (Dudley-Javoroski & Shields, 2013).

Gait training with walking frame, orthosis, body-weight exercises supported treadmill training (BWSTT), and exoskeleton is among the activities of a rehabilitation program with the main purpose to facilitate ambulation SCI persons. Besides that, there are some studies investigating its benefits on bone loss after SCI, but up to now, there is no good quality evidence in favor of this kind of intervention. Carvalho et al. (2006) showed that a BWSTT (30%–50% weight relief) with neuromuscular electrical stimulation, twice a week, for 20 min, for 6 months, in tetraplegic individuals led to elevate bone formation and reduce bone resorption markers, although the BMD did not enough. Another study with 12 months of BWSTT training did not increase bone density in individuals with chronic incomplete SCI, but BMD did not decrease at fracture-prone sites (Giangregorio et al., 2006). Other studies involving ambulatory orthosis also observed that walking did not improve BMD (Ogilvie, Bowker, & Rowley, 1993; Thoumie et al., 1995).

Karelis et al., in a case report, noticed little benefits on locomotor training using a robotic exoskeleton 3 times/week, for 6 weeks. A previous case report study did not find BMD benefits after robotic-assisted BWSTT (Lokomat) for 1 h activity, 3 times a week, in a period of 3 months, in an acute SCI. It is important to be careful about fractures occurring during this activity as cited by Zleik et al. Some studies suggested that low BMD may be a relative contraindication for the use of these devices (Zleik et al., 2019).

The bone loss prevention/treatment needs intensive body loading and for a long period in order to maintain body mass. Although there is no BMD cut-off value to preclude patients from participating in rehab interventions, an assessment of fracture risk is indicated before activities such as standing and walking to ensure its safety (Cirnigliaro et al., 2017; Craven et al., 2008). It is recommended to avoid exercises that result in torsion of the distal lower extremity or that have a risk of falling (Craven et al., 2008).

Although practices for increased mobility and weight-bearing are clearly important to skeletal health in SCI, there is not sufficient evidence in their capability to maintain BMD of the lower extremity (Zleik et al., 2019). In summary, there is low evidence that more than 5 h per week standing exercises could preserve tibial BMD in acute (less than 1 year) SCI cases (Soleyman-Jahi et al., 2018).

Electrical stimulation

Electrical stimulation (ES) and Functional Electrical Stimulation (FES) involve the use of surface or implanted electrodes to stimulate muscular activity. Whereas both methods typically employ cyclical patterns of electrical stimulation that simulate natural muscular activity, FES is directed toward the attainment of purposeful movement such as cycling or walking.

FES is the most extensively investigated approach since it combines the benefits from electrical stimulation and mechanical loading of the lower extremity long bones. Although FES intervention has been demonstrated to improve muscle atrophy, solid evidence from a large-scale study is still lacking regarding its influence on sub-lesional BMD attenuation.

FES studies enrolled participants with both acute and chronic injuries and are therefore difficult to classify as pure prevention or treatment interventions. In one review study, Bauman and Cardozo (2015) described that FES training administered at the time of acute injury appears to markedly reduced bone loss at the site applied or, if administered to those with chronic SCI, was also efficacious, albeit with a reduced magnitude of effect, at the place to which the load was applied. Soleyman-Jahi et al. (2018) investigated in a literature review the prevention- and evidence-based treatments for

osteoporosis related to SCI. They discovered low-quality evidence indicating that ES provided no significant effects. Very low-quality evidence did not show any benefit for low-intensity (3 days per week) cycling with FES in chronic SCI.

Chang et al. (2013) carried out a meta-analysis study to investigate whether bisphosphonate administration or functional electrical stimulation (FES) training could effectively decrease bone mineral. They noticed that FES cycling did not significantly decrease BMD loss in acute SCI individuals. Whereas, for people with a chronic SCI, BMD demonstrated a significant increase near the site of maximal mechanical loading. Furthermore, the studies employing FES $\geq$5 days per week were likely to have better effectiveness than studies using FES $\leq$3 days per week (Chang et al., 2013).

In the acute phase, there is a non-randomized trial reporting that FES cycling provided 1 to 3 months after SCI can partially reduce BMD loss in distal femur (Lai et al., 2010). In addition, the effect on the attenuation of bone loss in the distal femur diminished once FES cycling was discontinued (Lai et al., 2010). Eser et al. (2003) measured the effect of an FES cycling intervention on bone mineral density (BMD) of the tibia in recently injured SCI people in a non-randomized clinical trial. The intervention consisted of 30-min FES cycling three times a week for 6 months. They concluded that FES cycling was not effective for improving bone mass at the tibial mid shaft during the first year after injury.

For the chronic phase, the studies are conflicting, but the investigations that show improvement seem to be those with a longer period of training, which is 12 months or more, 5 times/week (Belanger, Stein, Wheeler, Gordon, & Leduc, 2000; Chen et al., 2005). It is also evident that all these studies measured their improvement corresponding to the trabecular bone, in particular in the distal femur or the proximal tibia.

FES cycling studies that reported a positive effect on bone parameters used protocols of at least 3 sessions per week for 6 months in duration. The increase in bone parameters was in areas directly affected by the stimulated muscles. Although a study showed that the FES cycling intervention needed to be maintained or bone gains were lost (Chen et al., 2005). Frotzler et al. (2009) found that BMD was preserved in the distal locations of some participants in 12 months. They concluded that the high-volume FES-induced cycle training had clinical relevance as it could partially reverse bone loss and thus may reduce fracture risk at this fracture-prone site.

The use of ES to clinical care has been fraught with difficulties due to the labor intensive nature of the present approaches and the appreciation that any effect on bone is rapidly lost, when the ES training is either reduced in frequency or terminated (Belanger et al., 2000; Eser et al., 2003; Lai et al., 2010). Considerations for FES efficacy in osteoporosis in SCI should consider attention to the duration, frequency, and power of the output (Chang et al., 2013; Dudley-Javoroski & Shields, 2013). Guidelines include intensities with loads of 1–1.5 times body weight, sessions of 3 or more per week for several months to 1 or more years, and safety considerations to prevent fractures (Dolbow et al., 2011). Craven et al. (2008) considered that ES and FES should be used with caution in patients with combined hip and knee flexion contractures of $>$30, a prior lower extremity fracture, severe lower extremity spasticity, and/or significant ankle plantar flexion contractures.

Finally, although the use of FES cycling looks promising, the limited availability of cycle ergometry for home or longitudinal use may limit its generalization, if therapy cannot be maintained outside a clinical trial environment. The quality of evidence available in this field is poor. Some results suggest physical activity could attenuate bone loss (Chain et al., 2012; Goktepe et al., 2004). Studies reported benefits on arm bone mass maintenance but did not prevent demineralization in the lower body (Goktepe et al., 2004). The type of activity and training intensity were not well-described, and many studies used a self-reported physical activity as a reference.

Physical activity

The quality of evidence available in this field is poor. Some results suggest physical activity could attenuate bone loss (Chain et al., 2012; Goktepe et al., 2004). Two of them reported benefits on arm bone mass maintenance but did not prevent demineralization in the lower body (Goktepe et al., 2004). The type of activity and training intensity were not well-described, and many studies used a self-reported physical activity as a reference. Miyahara et al. found that the earlier the athlete started sports after injury, the higher the BMD of the legs. Further, a longer period of athletic career after restarting was significantly related to higher leg BMD.

Vibration

The mechanical vibration used to prevent and/or treat the loss of BMD mixed results (Alizadeh-Meghrazi, Masani, Popovic, & Craven, 2012; Asselin, Spungen, Muir, Rubin, & Bauman, 2011). Similar to FES, the specifications of the chosen full-body vibration platform, including intensity and frequency of vibration, signal transmission, and joint position and angle, could play a role in effectiveness (Alizadeh-Meghrazi et al., 2012; Asselin et al., 2011).

Ultrasound

Ultrasound does not seem to play a role in preventing or treating osteoporosis. The only randomized study by Warden et al. (2001) did not indicate any benefit of low-intensity pulsed ultrasound to prevent decreased BMD. Therapeutic pulsed ultrasound was applied to the heel of individuals with spinal cord injury for 20 min a day, 5 times a week for a period of 6 consecutive weeks. The contralateral heel was simultaneously treated with inactive United States. No improvement was observed in any of the parameters evaluated ($P > .05$). According to the authors, this finding may be related mainly to the inability of the US to effectively penetrate the external cortex of the bone due to its acoustic properties.

Combined treatments

There are few evaluated studies that combined interventions for the treatment of bone loss in chronic SCI. These studies assess the concomitant administration of pharmacological therapy with non-pharmacological rehabilitation interventions (Gordon, Wald, & Schnitzer, 2013; Morse, Biering-Soerensen, et al., 2019; Morse, Troy, et al., 2019). Morse, Biering-Soerensen, et al. (2019) and Morse, Troy, et al. (2019) investigated the combination of zoledronate (ZA) with FES-rowing. The results demonstrated that the osteogenic response to FES-rowing was dose-dependent and combination therapy with ZA and FES-row training had therapeutic potential to improve bone quality, and perhaps reduced fracture risk at the most common fracture site following SCI. Gordon et al. (2013) evaluated the response of bone to recombinant parathyroid hormone in combination with weight bearing. The results did not show a statistically significant increase in BMD of the lumbar spine (Gordon et al., 2013).

Conclusion

Special attention should be paid to prevent fractures, and appropriate treatment for preventing excessive bone loss and investigations should be performed in rehabilitation hospitals for patients with SCI. Most of the physicians are not educated to measure these risk factors. DEXA should be performed, mainly after an osteoporotic fracture and in fact DEXA should be performed before the occurrence of fracture to prevent such event. Bone remodeling markers (like CTX-I) could give us a clue of the resorption rate and treatment could prevent further loss. Consider identifying risk factors and establishing prevention programs and appropriate treatment. Campaigns to prevent falls and stimulate the appropriate identification and treatment of osteoporosis in individuals with SCI must be promoted.

The analysis of literature for treatments still show mixed results, although there is no guideline, treatment with pharmacological therapy should be considered for patients with SCI, risk factors for fractures and DEXA criteria for osteoporosis. Use of oral bisphosphonates as alendronate or intravenous zoledronic acid, have showen efficacy but further studies should be performed.

The studies suggest standardization of the osteometabolic evaluation of patients with SCI, it is recommended undergo to laboratory evaluation before treatment, 6 months after beginning pharmacological therapy and repeated on annual basis. DEXA should be performed before treatment, 1 year after and every 2 years. Discussions with patients about side effects of these medications are recommended. It is important to emphasize that the protection of typical fractures is greater than the side effects when used for the appropriate length of time.

The effects of non-pharmacological measures are insufficient as a sole modality for osteoporosis prevention and treatment. Several literature reviews were conducted along the time and realized that studies on the use of physical therapies to prevent bone demineralization were inconclusive. The detection of an effective clinical intervention in this study area will require rigorous minimization of bias through a randomized controlled clinical trial design and likely require the involvement of multiple centers. It will also be dependent on appropriate measurement, with adequate intensity and duration of the intervention to detect a treatment effect. However, given the difficulty in conducting large-scale randomized controlled trials to address these issues, many of these gaps can best be addressed by using a multi-faceted approach including a combination of literature synthesis, large longitudinal observational studies and an expert opinion. Any prospective intervention is likely to benefit from early timing after acute SCI.

Before a treatment prescription, it is important to take into consideration timing since SCI, type, frequency, intensity and duration of intervention and the patient's possibilities to follow-up with a long-term treatment. Exercise and pharmacological prescriptions have to be safe. The patient has to be informed about the treatment evidence, risks, benefits and burdens of each alternative (including no intervention) and, together, make a shared decision, depending on their goals, preferences and concerns.

Applications to other areas of neuroscience

In this chapter, we have reviewed the effects of osteoporosis after spinal cord injury and related fractures.

Osteoporosis after SCI is defined as an excessive bone resorption after SCI and bone fragility fractures caused by a trauma that would be insufficient for a normal bone to fracture (Craven et al., 2008; Zleik et al., 2019) or by minimally loaded situations (McPherson et al., 2014; Shields et al., 2005).

Osteoporosis is the most common silent disease in humans whose complication is fragility fractures. Osteoporosis is a treatable disease before fracture occurrence, and even if the first fracture occurred, there is benefit to prevent a new event.

Osteoporosis investigations should be performed for spinal cord injury, traumatic brain injury, neuromuscular disorders, and others because osteoporosis-related fractures in patients with chronic disabilities are a complication with consequences in activities of daily living and rehabilitation (Champs et al., 2020).

Dual-energy X-ray absorptiometry is an important method for diagnosis and should be performed in all patients with chronic disabilities (Garland et al., 2005).

The effects of non-pharmacological treatments are under debate, and studies showed the efficacy of bisphosphonates and Vitamin D to prevent fragility fractures (Bauman, Spungen, et al., 2005; Bauman, Wecht, et al., 2005; Gilchrist et al., 2007; Zehnder et al., 2004).

Campaigns to prevent falls are needed because falls are the first event related to fragility fractures (Champs et al., 2020).

Mini-dictionary of terms

Osteoporosis: According to the WHO, osteoporosis is defined as a low bone mass and micro-architectural deterioration of bone tissue with a consequent increase in bone fragility and susceptibility to fracture.

Fragility fractures: These are fractures caused by a force that usually doesn't cause a fracture as torsional forces during transfer, compressive forces, unknown, fall from wheelchair, self-passive mobilization, exercises, findings on X-ray, orthostatism or walking training, and others. Fractures because of fall from greater than standing height, sports injuries, and motor vehicle/motor cycle accidents are excluded.

Spinal cord injury: Damage of the spinal cord can be traumatic because of motor vehicle/motor cycle accidents, falls, and others or can be non-traumatic because of virus, tumors or demyelinating disorders, and others.

Dual-energy X-ray absorptiometry (DEXA): It calculates the measurement of bone mineral density in g/cm^2, is a confirmatory test to predict the future risk of fracture, and also serves for ongoing monitoring of bone health and to access bone loss by the bone mineral density (BMD) measurements.

Bisphosphonates: These are drugs capable to inhibit bone resorption.

Key facts of osteoporosis after spinal cord injury

- Bone demineralization after SCI occurs in a rate loss of approximately 4% per month in the first year, and bone loss can be extended 3 to 8 years after SCI.
- Bone loss associated with SCI is related to immobility and metabolic changes.
- Other related factors may contribute to this bone loss, such as vitamin D deficiency and the use of methylprednisolone, anti-convulsant drugs, and psychotropic substances.
- Studies demonstrated bone demineralization greater than 20% to 70% in lower limbs after SCI.

Key facts of fragility fractures after spinal cord injury

- The consequence of osteoporosis in individuals with SCI is fracture due to bone fragility.
- It usually occurs in transfers, falls and activities with minimal or no trauma.
- Fractures may occur in 25% to 46% of these people with SCI over their lifetimes.
- Most places of fractures are in the tibia and/or distal fibula, distal femur, or hip/proximal femur and proximal tibia.

Key facts of diagnosis of osteoporosis after spinal cord injury

- Osteometabolic evaluation of patients with SCI is recommended for evaluation before treatment, 6 months after beginning pharmacological therapy and repeated on annual basis.

- DEXA should be performed before treatment, 1 year after and every 2 years.
- DEXA measurement of the distal femur and proximal tibia, with specific protocols for the evaluation of these sites, is recommended.

Key facts of treatment for osteoporosis-related fractures after spinal cord injury

- Treatment with pharmacological therapy should be considered for patients with SCI and risk factors plus DEXA criteria for osteoporosis.
- The effects of non-pharmacological measures are insufficient as a sole modality for osteoporosis prevention and treatment.
- Discussions with patients about side effects of these medications are recommended.
- The patient has to be informed by a healthcare professional about the treatment evidence, risks, benefits, and burdens of each alternative (including no intervention), and together make a shared decision, depending on their goals, preferences, and concerns.

Summary points

- Osteoporosis affects the health of individuals with SCI because it increases the risk of fragility fractures with consequences.
- Most sites of fractures are in the tibia and/or distal fibula, distal femur, or hip/proximal femur and proximal tibia.
- Fractures are primarily related to torsional forces during transfer, passive mobilization, compressive forces, and falls.
- Special attention should be paid to the prevention of fractures, appropriate treatments should be instigated to prevent excessive bone loss, and investigations should be performed.
- Campaigns to prevent falls and stimulate the appropriate identification and treatment of osteoporosis in individuals with SCI must be promoted.
- Dual-energy X-ray absorptiometry (DEXA) is an important method for diagnosis.
- Treatment with pharmacological therapy for people with SCI with risk factors for SCI population should be considered.
- The patient has to be informed about the diagnosis and treatment options and make a shared decision for treatment, depending on their goals, preferences, and concerns.

Introduction

Compression of the cervical spinal cord can be caused by a wide range of causes, but the most common is cervical spondylosis (CS), a chronic degenerative process that affects the vertebral bodies and inter-vertebral discs of the cervical spine (Table 1). CS is frequently found in asymptomatic adults after the fifth decade of life, but may progress to disk herniation, bone spur formation, compression of the spinal cord, and cervical spondylotic myelopathy (CSM) (Kelly, Groarke, Butler, Poynton, & Byrne, 2012).

The compression of the spinal cord by CS is a slow and progressive process caused by the reduction of the spinal canal diameter by dynamic and static factors (de Oliveira Vilaça et al., 2016). In CS, any flexion or extension of the cervical spine causes the intermittent compression of the spinal cord. This progressive compression leads to several changes such as apoptosis of the anterior horn neurons, ischemia, gradual spongy necrosis, demyelination of the white matter (WM), and Wallerian degeneration (Fig. 1; Grabher, Mohammadi, David, & Freund, 2017). Despite it may affect one single segment of the

Diagnosis and Treatment of Spinal Cord Injury. https://doi.org/10.1016/B978-0-12-822498-4.00008-7

TABLE 1 Summary of the main causes of spinal cord compression.

Traumatic causes	Atraumatic causes
Vehicular accidents	Degenerative spondylosis
Falls	Intervertebral disk herniation
Violence	Metastatic disease
Sports	Primary spinal cord tumor
Recreation activities	Spinal epidural abscess
	Spinal epidural hematoma
	Scoliosis
	Rheumatoid arthritis
	Bone diseases

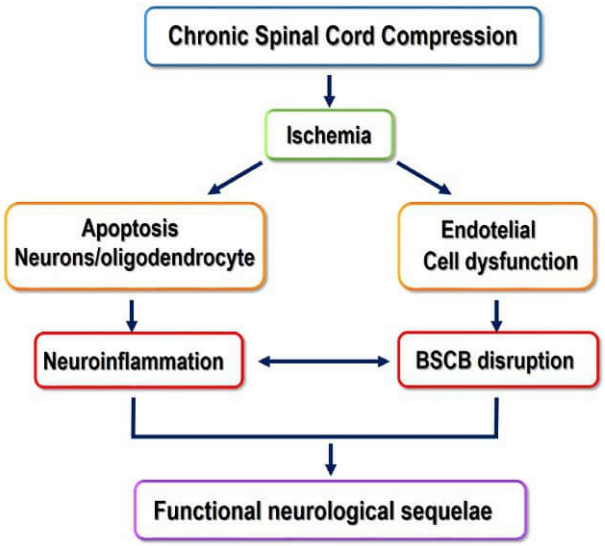

FIG. 1 Representative scheme of the pathophysiology of cervical spondylotic myelopathy. Chronic compression of the spinal cord causes chronic ischemia that damages oligodendrocytes and neurons eliciting an inflammatory response, endothelial cell loss, and disruption of the blood-spinal cord barrier (BSCB). Neuronal loss and axonal damage lead to neurological impairment. *Unpublished figure*.

spine, multi-level involvement is very frequent, generally at the lower segments. Contrary to the lumbar spine, which encloses only a small part of the spinal cord, stenosis of the cervical spinal canal can induce a direct compromise of the whole spinal cord and severe neurological deficits.

Characteristically, in CS, the severity of compression and deficits varies greatly across individuals. Some patients experience a benign form of the disease with stable periods lasting from months to years, while others develop CSM with neurological deficits and a considerable deterioration over time (Baron & Young, 2007; Edwards, Riew, Anderson, Hilibrand, & Vaccaro, 2003). If CSM fully develops, the symptoms are progressive and in a stepwise manner (de Oliveira Vilaça et al., 2016), with a wide range of clinical manifestations including weakening or sensory loss in one or more limbs, gait unsteadiness, fine motor deficits, and non-specific neck and shoulder pain with or without radiculopathy.

Diagnosis of CSM is based on physical examination and clinical imaging, usually with Magnetic Resonance Imaging (MRI). MRI allows to evaluate the vertebral discs, ligaments, subarachnoid space, spinal cord, and quantify the spinal stenosis. Still, it lacks sensitivity to provide information about the integrity of the spinal cord, presents a poor correlation with neurological and functional impairment, and does not provide reliable prognostic information to predict surgical outcomes (Martin et al., 2016). Recent advances in MR techniques have started to overcome these limitations by providing invaluable information about CSM pathology, with several studies reporting that prolonged cervical spine compression affects not

only local structures but also distally from the site of injury. For instance, numerous brain changes, such as cortical and subcortical atrophy, functional reorganization of the sensorimotor cortex (SMC), and connectivity impairment, have been reported (Bernabéu-Sanz, Mollá-Torró, López-Celada, Moreno-López, & Fernández-Jover, 2020; Chen et al., 2017). These observations have had a great impact on the understanding of CSM, framing the disease as multi-factorial and complex, with its pathophysiology still being poorly understood. In this sense, a clear limitation to advancing in the field of CSM pathology has been the lack of reliable animal models.

Understanding the sequence of structural and functional changes of CSM at the brain level, and defining their effects on the clinical outcome is of crucial importance to better understand the disease, to prevent its fatal consequences, and to develop the best evidence-based rehabilitation therapies. In the next sections, we will summarize the current knowledge on the effects of prolonged spinal cord compression on the brain (Figs. 2–5).

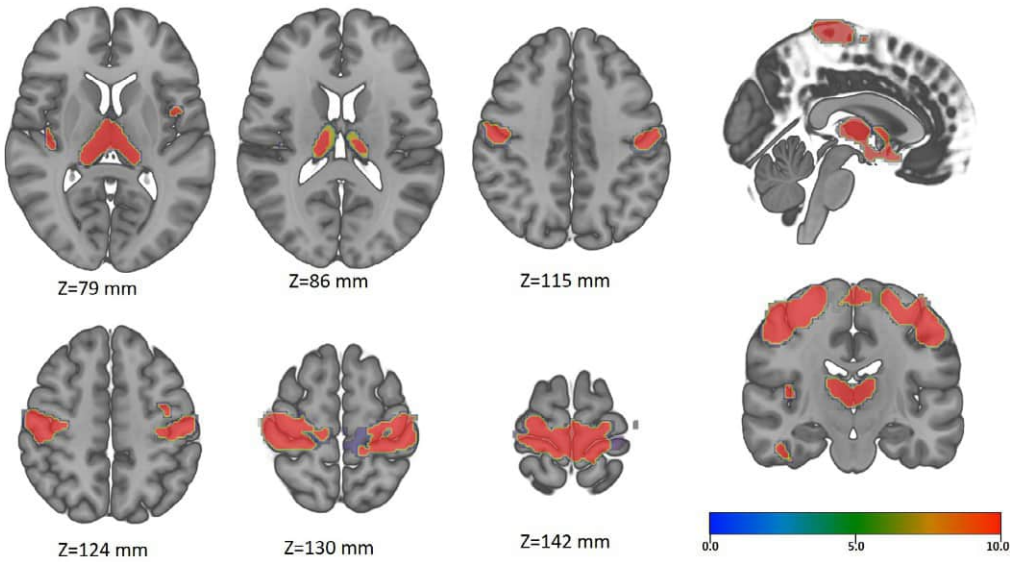

FIG. 2 Representation of the regional areas with significant cortical volume reduction in a group of patients with prolonged cervical spine compression. The results were obtained from a voxel-based morphometry analysis in a group of 64 subjects (32 cervical spondylosis patients vs. 32 healthy controls, $P < .05$ corrected), suggesting that prolonged cervical spine compression led to thalami, sensorimotor cortex, and supplementary motor area atrophy. *Unpublished figure*.

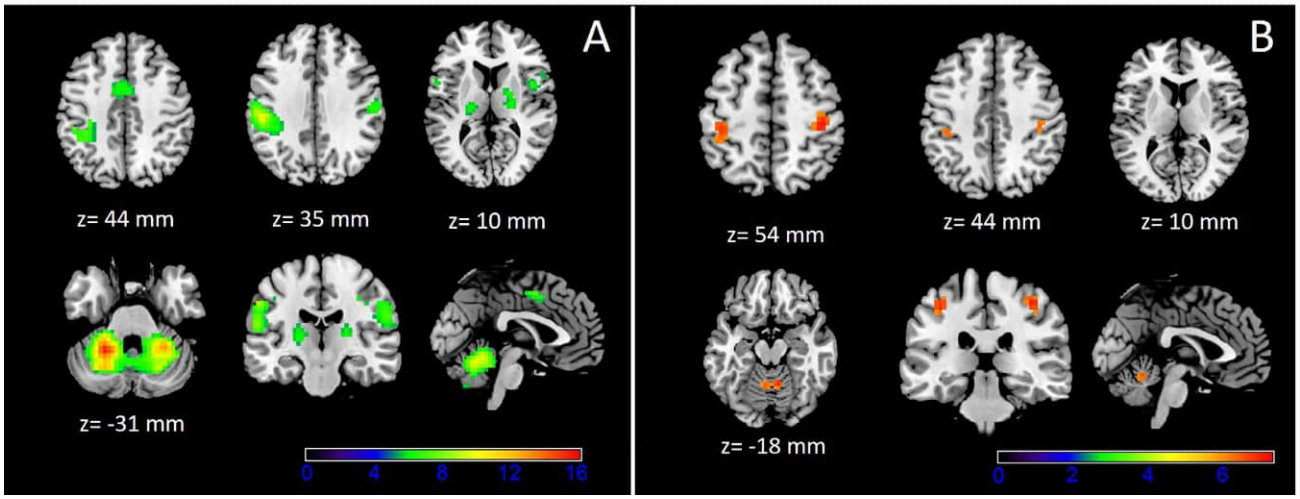

FIG. 3 Functional MRI results showing the differences in the brain activation pattern in a group of cervical spondylosis patients ($n = 32$) (A) and age-matched healthy controls ($n = 32$) (B) during a bilateral finger-tapping task. The activation maps correspond to a second-level analysis in axial, coronal, and sagittal planes in the MNI space ($P < .05$ corrected, $k = 10$). The patients presented a higher number of activated cortical and subcortical areas than healthy controls. *Unpublished figure*.

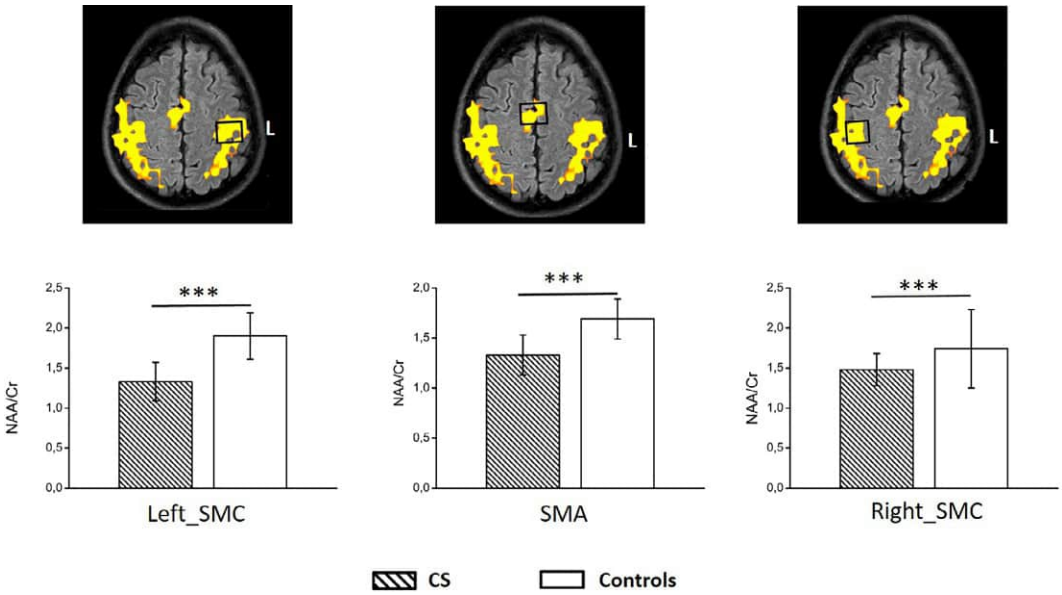

FIG. 4 MR-spectroscopy results of the motor cortex of cervical spondylosis patients (CS, n=32) and healthy controls (HC, n=32). The volume of interest was located on the activated area in both the primary sensorimotor cortex (SMC) and supplementary motor area (SMA) after a bilateral finger-tapping fMRI task paradigm (see *upper image* as example of voxel location for measurements). Graphs represent the NAA/ Cr (mean ± SD) values obtained after quantification in each group. A significant reduction was observed in all areas compared to controls suggesting significant neuronal/axonal damage. *** represents $P < .001$ after unpaired t-test. *NAA*, N-acetylaspartate; *Cr*, creatine. *Unpublished figure*.

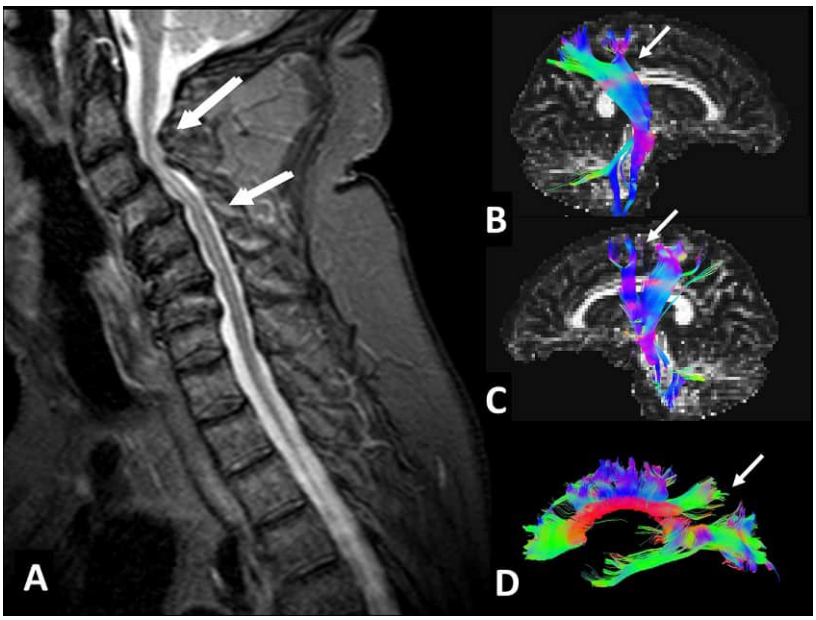

FIG. 5 Tractography results obtained in a patient with cervical spondylosis myelopathy. (A) Sagittal STIR of a 69-year-old male with cervical spondylosis and myelopathy at C2-C5 levels, significant cervical lordosis loss, and several diffuse herniated discs from C2 to C7. Clinically the patient only presented bilateral manual clumsiness. No cervicalgia or cervicobrachialgia was present. (B, C, D) Tractography results suggested significant bilateral and symmetrical axonal damage affecting both corticospinal tracts at the distal-anterior regions (B, C) and the *corpus callosum* (A) at the superior and posterior parietal projection fibers of both hemispheres *(see arrows)*. Commissural fibers were preserved. *Unpublished figure*.

Cervical spine compression causes brain atrophy

There is increasing evidence supporting that spinal cord injury (SCI) may cause destructive cortical changes ranging from atrophy of projecting neurons to cell death (Freund et al., 2013; Hains, Black, & Waxman, 2003). In animal models, after SCI, the disruption of the motor efferents and sensory afferents results in atrophic changes of the neural sensorimotor systems (Hains et al., 2003). Indeed, several studies have demonstrated that SCI can induce cortical atrophy on the supraspinal network, whose degree correlates with the spinal cord atrophy (Freund et al., 2011, 2013) and the functional status (Freund et al., 2011).

There are still a few works exploring the effect of prolonged spinal cord compression by CS in the brain. However, the results are consistent reporting cortical atrophy in the primary SMC, with additional volume changes at the thalami, specifically at the pulvinar nuclei (Bernabéu-Sanz et al., 2020; Woodworth, Holly, Mayer, Salamon, & Ellingson, 2019). Furthermore, supplementary brain areas related to the execution of complex movements (such as gait, grasp, and fine hand-motor coordination) are also atrophied (Bernabéu-Sanz et al., 2020; Woodworth et al., 2019). Metabolic studies using MR-spectroscopy on CSM patients have also reported neuronal damage and impaired metabolism on the SMC that is not recovered or may worsen after surgery in spite of clinical improvement (Aleksanderek et al., 2017; Goncalves, Stevens, Doyle-Pettypiece, Bartha, & Duggal, 2016).

In a recent study regarding chronic CS, a consistent pattern of brain changes associated with neurological function and neck pain was observed (Woodworth et al., 2019). Specifically, cortical thinning in the superior frontal regions, anterior cingulate, insula, and precuneus were present. Furthermore, atrophy in the putamen, BA3a, and primary motor regions when worsening neurological symptoms was reported. Taking into account the role of BA3a as an afferent receiver of proprioception (Panchuelo et al., 2020), the observed atrophy in this study may explain the deficits in proprioception (gait and hand function) reported in CSM patients (Theodore, 2020).

CS patients may also present brain changes to chronic pain in the same fashion as other chronic pain conditions. Specifically, a cortical thinning within the insula and anterior cingulate cortex has been reported (Freund et al., 2011). Finally, a faster rate of cortical thinning and atrophy compared to age-matched healthy subjects in CS patients has been observed (Woodworth et al., 2019).

The significance of these findings is that despite CS has been traditionally considered as a benign disease typically present in the old-age population, it may, if not properly monitored, harm the brain inducing progressive atrophy. In this sense, the CS-related brain atrophy may become a potential obstacle to clinical recovery after surgery, even if significant repair is achieved at the site of compression.

Cervical spine compression causes neural plasticity to preserve function

One of the most fascinating characteristics of the central nervous system is its ability to self-repair, reorganize after injury, and compensate for functional loss. This mechanism, known as neural plasticity (or functional reorganization), is present in numerous brain conditions (Cohen, Quarta, Bravi, Granato, & Minciacchi, 2017) and has also been observed in SCI. The exact mechanism is not fully understood but may occur through synaptic modifications of pre-existing connections and/or by the development of new circuitries (Holly, Dong, Albistegui-DuBois, Marehbian, & Dobkin, 2007).

Several studies have shown that SCI, although it does not directly involve cortical neurons, may alter the functional activation pattern of the SMC. These observations have been achieved with different physiological and imaging techniques such as functional MRI (fMRI). fMRI is a non-invasive imaging modality that allows to detect changes in brain activation over a period of time while a specific task is being performed. It can be used to localize areas of brain activation secondary to several cognitive and motor tasks, allowing to map the cortical representation of neural activation (Buchbinder, 2016).

In CSM patients, fMRI studies have shown the existence of significant changes in the cortical activation pattern during sensorimotor tasks. These changes consist of the expansion of the cortical representation for the affected limb by the inclusion of adjacent motor territories (Dong et al., 2008). Recruitment of supplementary areas outside the SMC including *globus pallidus*, left thalamus, caudate nucleus, and both cerebellum hemispheres have been reported. Additionally, decreased activation in SMA and both SMC, as well as increased activation of both cerebellum hemispheres, has been observed (Bernabéu-Sanz et al., 2020). Interestingly, the displacement and activation of the sensorimotor areas in CSM appeared in the vicinity of the areas with gray matter (GM) atrophy, suggesting that the displacement and recruitment of new cortical areas may be mediated by adaptive changes to GM atrophy (Henderson, Gustin, Macey, Wrigley, & Siddall, 2011). This functional reorganization is closely associated with the severity of the SCI (Zhou et al., 2015), helping to maintain a residual motor function, and contributing to its restoration if the disease progression is halted (Dong et al.,

2008). Indeed, these adaptive changes may also explain why some CSM patients with significant SCI are able to perform motor activities with apparently minor neurological deficits.

Comparison of pre-operative and post-operative studies has shown that surgical decompression of the cervical spine leads to cortical reorganization, probably by the recovery of conduction in the preserved axons at the spinal cord (Green et al., 2015). After surgical decompression, the altered SMC recruitment pattern gradually disappears (Holly et al., 2007), and everything progresses toward an activation pattern similar to the observed in healthy controls (Dong et al., 2008). There is an increased activation in the contralateral primary motor cortex (M1) concomitant with the improvement of the motor function and the extent of spinal cord expansion (Bhagavatula et al., 2016; Tam, Barry, Bartha, & Duggal, 2010). Also, a gradual disappearance of the ipsilateral primary SMC activation in addition to a progressive increase in the contralateral SMC and SMA is observed (Dong et al., 2008). This normalization continues over time and can be enhanced by activity-dependent mechanisms related to task practice and learning.

In summary, according to recent studies, CSM patients present compensatory mechanisms that consist of an increase and expansion of the cortical representation of the motor areas, especially those devoted to the hands. After the surgery, there is a tendency to normalization of the sensorimotor representation. However, the reported results are not completely consistent. This is probably because CSM patients form a heterogeneous group with different levels of impairment, different degrees of SCI, and different natural histories. In addition, there is no uniformity in the timing of imaging after the surgery. Still, the reported observations provide direct evidence of neuronal plasticity in the SMC of CSM patients that may play a main role in the post-operative motor functional recovery.

Cervical spine compression changes the functional connectivity of the brain

Few studies have analyzed the alterations of the whole-brain network in CSM. These studies have been performed with resting-state functional MR imaging (RS-fMRI), a new technique that allows evaluating the functional relationship between brain areas, and enables the visualization of brain functional connectivity (FC) between spatially separated brain regions. RS-fMRI is a robust method that uses the endogenous brain activity detectable with blood oxygen level-dependent (BOLD) to identify areas that are interacting at rest. With RS-fMRI spontaneous low-frequency BOLD-fluctuations in neural activity (known as amplitude of low-frequency fluctuation) are detected, allowing to establish the different anatomically correlated functional networks (Smitha et al., 2017). As a result, the resting-state networks (RSNs) maps are obtained which represent topographies of functionally connected regions across the brain, helping to detect functionally relevant changes after injury to the central nervous system, if present.

In CSM, RS-fMRI studies have reported that compression of the cervical spinal cord alters the connectivity pattern of the sensorimotor and visual cortices of the brain. Specifically, an overall increase in the FC in the sensorimotor cortex and supplementary areas (precuneus, superior frontal gyrus, and anterior cingulate), and between the cerebellum and the pre- and post-central gyri has been reported. This increased FC correlates with the worsening of the neurological symptoms, suggesting that the altered FC between the SMC and supplementary areas might represent compensatory mechanisms for accomplishing motor tasks (Woodworth, Holly, Salamon, & Ellingson, 2018).

In a recent study, increased brain activity in the primary SMC and decreased brain activity in visual cortices and both supramarginal gyri (SMG) were observed. Characteristically after surgical decompression, the brain activity of the sensorimotor and visual cortices normalized (Takenaka et al., 2019). In another study by Chen et al., the authors only reported decreased neural activity in the primary visual cortex of CSM patients and an increased FC between the visual cortex and the posterior cingulate lobe (Chen et al., 2018). These observations suggested that the visual cortices were impaired, which accounted for the blurred vision observed in the patients of the study. Interestingly, the visual impairment also improved after surgical decompression. Considering that the cingulate gyri are related to the dorsal attention network, that in turn is involved in the control of visual attention (Fox, Corbetta, Snyder, Vincent, & Raichle, 2006), the authors concluded that the enhanced FC in the visual attention network was an adaptive mechanism to compensate for the diminished activity observed on the primary visual cortex.

In another study, increased FC between the left thalamus, the visual system (bilateral lingual gyrus, cuneus), and the right cerebellum posterior lobe, that correlated with the sensory scores (Peng, Tan, He, & Ou, 2020), were found. Moreover, decreased FC between the sensory and motor cortices was observed. The authors concluded that the increased FC in the visual-related network acted as a compensatory mechanism to the decreased somatosensory transmission information detected in the patients. Likewise, increased FC between the brainstem and visual cortex in both posterior parietal cortices and its association with neurological impairment and neck disability has been described in CSM (Wang, Laiwalla, Salamon, Ellingson, & Holly, 2020).

While the altered FC in the SMC is in line with previous fMRI literature during sensory and motor tasks, the observation of increased FC in the visual cortex is surprising as CS is not a primary visual disorder. In this sense, Wang et al. propose that the observed increased FC in the visual cortex may be secondary to the need for more visual input to optimize body movements, mechanics, and balance (Wang et al., 2020). This observation is in line with the work of Chen et al., where the authors suggest a compensatory compensation for the insufficient input from the proprioceptive system (Chen et al., 2018).

In summary, brain plasticity is present in CSM patients to overcome functional deficits. The main changes are long-term FC reorganizations in the sensorimotor regions and areas assisting in the regulation of movement and sensory perception. This altered connectivity between various sub-networks may have prognostic potential and/or therapeutic implications in CS patients.

Cervical spine compression also damages the brain WM

Progressive chronic compression of the spinal cord also results in many pathological changes in the WM that are detectable using diffusion tensor imaging (DTI). DTI is an MRI technique that allows the evaluation of micro-structural changes in the WM by measuring the motility and orientation (anisotropy) of water molecules in tissues. DTI evaluates several parameters, the most important are: (1) mean diffusivity (MD), and (2) fractional anisotropy (FA). FA is a scalar value between 0 and 1 that evaluates the preferred direction of which diffusion occurs in the central nervous system and is the most sensitive parameter to detect SCI (Guan et al., 2017). FA is largely attributed to the transverse axonal barriers in WM (i.e., myelin sheath, axon membrane) restricting the water diffusion to a preferred longitudinal orientation. Reduced FA values indicate a disturbance in the directional orientation of nerve fibers and are associated with reduced myelin integrity (Chen et al., 2017).

In CSM, most of the DTI studies have been centered on the local changes at the spinal cord, reporting differences in diffusion characteristics of the water molecules at the site of compression, that are associated with increased neurological dysfunction (Ellingson, Salamon, Grinstead, & Holly, 2014; Guan et al., 2017; Martin et al., 2016). Specifically, decreased FA values have been found in stenotic segments (Guan et al., 2017) in the lateral and posterior column of WM suggesting significant myelin damage (Cui et al., 2014). Likewise, decreased FA values and increased MD values have been found in CS patients in the early stages of the disease even in cases without visible myelopathy in the MRI examination (Banaszek, Bladowska, Szewczyk, Podgórski, & Sąsiadek, 2014); suggesting that DTI presents higher sensitivity in myelopathy detection compared to conventional MRI.

In the brain, current studies in SCI have mostly analyzed the effect of traumatic etiology. In these reports the results show WM damage in supraspinal areas along the corticospinal tracts in the medulla, pons, midbrain, posterior limbs of the internal capsule (Freund et al., 2011, 2013; Guleria et al., 2008), and both centrum semiovale (Koskinen et al., 2014). Furthermore, the CST damage correlates with the brain functional reorganization, the lower cross-sectional spinal cord area, and the upper limb ability (Freund et al., 2012). Characteristically, this WM damage starts early after the traumatic SCI, with a pronounced and progressive decrease of the spinal cord area concomitant with a reduction in the cranial CST and GM volume at the SMC (Freund et al., 2013). These changes are assumed to be induced by retrograde degeneration along the CST axons that over time results in shrinkage of the soma of corticospinal projecting neurons. Overall, the studies in traumatic SCI suggest widespread changes in WM micro-structure in the CST and in areas adjacent to the SMC that in turn associate with the clinical state of the patients.

Although there are few reports on CS, similar results have been found suggesting that CS causes anterograde and retrograde degeneration of the spinal WM tracts, resulting in axonal loss and demyelination that may extend cranially to cerebral regions. For instance, micro-structural changes in the ventral horns above the level of injury that correlated with diffusivity changes in the CST have been observed (Grabher et al., 2017). Similarly, Wen et al. observed WM damage at the region of the CST that correlated with the myelopathy severity in CSM patients (Wen, Cui, Mak, Luk, & Hu, 2014). Thus, both studies suggest a direct association between neurodegeneration affecting the motor system at the spinal cord, the CST integrity, and clinical impairment.

Characteristically, in CS patients, significant WM damage at both CST independently of the affected limb and *corpus callosum* has been reported. At the corpus callosum, significant damage to the superior and posterior parietal projection fibers, areas related to motor and touch-stimulation (Fabri, Pierpaoli, Barbaresi, & Polonara, 2014) were observed. Tractography results on CS patients also suggested a common pattern of WM damage, being affected the anterior-distal segments, regions directly linked to the motor cortex. The preserved regions at both CST were those arising from S1, which are more posterior and medial than those of M1 and thus less vulnerable to compression. Besides, a direct association between the damage at the CST, the clinical scores, and the evolution after surgery was observed (Bernabéu-Sanz et al., 2020). These

observations suggest that CST metrics with DTI may be used as a potential biomarker in the clinical setting to determine the impact of the disease and predict outcomes (Bernabéu-Sanz et al., 2020).

The CST is the largest descending pathway that connects the motor cortex to the brain stem and spinal cord and is mainly responsible for the movement of the distal extremities, particularly fine motor activities of the hand (Jang, Medicine, & Medicine, 2014). It is particularly vulnerable to the negative effects of cervical spinal compression suffering early demyelination. Recent reports on SCI both of traumatic and compressive origin suggest that the predominant pathological mechanism on both conditions is the demyelination of the ascending and descending CST fibers, leading to a progressive loss of axonal conductivity (Dong et al., 2008), with additional connectivity impairment between the SMC and the brainstem (Wang et al., 2020). The impact of the CST damage in the brain cortex has been previously described in other pathologies such as stroke. In these patients, whereas the degree of CST injury strongly predicts the resulting motor impairment (Lotze et al., 2012; Stinear et al., 2007), the neurological function tends to be preserved by the reorganization and recruitment of new pathways as well as other motor network nodes to optimize the residual neurological function (Pantano, Petsas, Tona, & Sbardella, 2015; Ward, 2011). In this sense, it is believed that most of the axotomized CST neurons are able to maintain the sensory-motor circuits through axonal sprouting (Zdunczyk et al., 2018). However, if CST neurons are damaged, whittling down the population by spinal compression over time may lead to some critical threshold to impairment. This could be the reason why some CSM patients do not present a significant clinical improvement of their symptoms after surgery.

In summary, spinal cord compression leads to significant WM damage mainly at the corticospinal tracts leading to a progressive loss of axonal conductivity that extends cranially to the brain. This reduced connectivity associates with the neurological impairment and may constitute a potential barrier for motor recovery after surgery.

Conclusion and future perspectives

As the population ages, the incidence of CSM will increase, but the knowledge of the effects of CSM in the brain is still sparse. On the other hand, there are no high-evidence studies providing well-founded recommendations for the best treatment modality. Considering that CSM has a potentially devastating outcome more studies are needed to better clarify the evolution of the disease and its consequences. Furthermore, to improve clinical outcomes the strategies should be equally targeted on the recruited adjacent cortex and the primary SMC. In this framework, we propose that increased collaborations among clinicians, experts in neuroimaging techniques, and basic researchers will enhance our ability for a better management of the disease.

Applications to other areas of neuroscience

Cervical spondylosis myelopathy (CSM) is the major cause of disability in the elderly and, despite significant ongoing research, current therapeutic approaches have limited effectiveness and are far from satisfactory (Shiban & Meyer, 2014). One potential barrier is that current treatments generally assume intact neural motor systems for driving limb movements, but we should consider that this condition can lead to neuronal damage distal to the spinal lesion and cerebral reorganization. Therefore, the brain atrophy and the damage of cortical pathways in CSM could become a potential obstacle for achieving full and effective function recovery, even after successful surgical repair at the site of compression.

Advanced neuroimaging techniques can be applied to detect specific secondary brain damage in CSM. However, brain reorganization is not a static process, but rather very dynamic. Cortical reorganization starts early after spinal cord injury, and its impact over time will depend on a complex balance between spinal recovery and supraspinal reorganization (Freund et al., 2013). Thus, it is crucial to better understand how the brain reorganizes after the injury, as well as develop cost-effective therapies to maximize functional recovery. In this framework, therapies designed to enhance brain plasticity could provide functional benefits for these patients both before and following surgery (Sharma, Classen, & Cohen, 2013).

The findings of a progressive degenerative pattern in spinal cord compression suggest the need to properly monitor the disease. Advanced Magnetic Resonance techniques may present a main role in non-invasive assessment to better predict the patient's outcome as well as to identify the patients that will most likely benefit from different therapies and prioritize which patients will precise surgery more urgently.

Mini-dictionary of terms

Cervical spondylosis: Term to define the progressive degenerative changes that affect all the components of the cervical spine (i.e., inter-vertebral discs, facet joints, joints of Luschka, ligamenta flava, and laminae).

Cervical spondylosis myelopathy: Term to define injury to the spinal cord due to severe compression caused by cervical spondylosis.
Corticospinal tract: White matter motor pathway that connects the cerebral cortex with the lower motor neurons and interneurons in the spinal cord.
Diffusion tensor imaging: MR technique based on the diffusion of water molecules of the tissues that allows to obtain information about the white matter architecture and integrity.
MR-spectroscopy: MR technique that allows to obtain the chemical composition of tissues, it is used to explore in vivo tissue metabolism and to detect and monitor several pathologies.
Functional magnetic resonance imaging: A technique that allows to obtain the brain activation pattern of a subject while performing a specific task. It is commonly used in the clinical setting to map cortical-activated areas before surgery to preserve their function. It is also widely used in research to study differences in brain activation patterns.
Functional reorganization: Also known as neural plasticity, neuroplasticity, or brain plasticity. The ability of the central nervous system to adapt in response to lesions or changes in the environment. This process could be accomplished through the recruitment of new/different neural networks, changes in the connectivity pattern, and the formation of new synapses.
Resting-state functional magnetic resonance imaging: A technique that allows to obtain the connectivity pattern of functional brain areas at rest that are spatially separated.
Sensorimotor cortex: Brain area located at the pre-central and post-central gyri which contain the primary motor and somatosensory areas of the brain.
Supplementary motor area: Brain area located in the midline cortex, anterior to the primary motor cortex that is responsible for movement control and coordination.

Key facts of spinal cord compression

- The most common cause is cervical spondylosis which is frequently found in asymptomatic adults after the fifth decade of life.
- Cervical spondylosis may progress to cervical spondylosis myelopathy, a progressive condition that causes incomplete spinal cord injury and associated neurological impairment in a stepwise manner.
- At present most of the studies have been focused on the local changes at the cervical spine, showing apoptosis of the anterior horn neurons, gradual spongy necrosis, demyelination of the white matter, and Wallerian degeneration.
- Cervical spondylosis may present some similarities with traumatic spinal cord injury.
- Cervical spondylosis leads to adaptive changes in the brain to compensate for the functional loss, causing a wide range of clinical manifestations.

Key facts of advanced MRI techniques

- Present high sensitivity to detect neural damage secondary to cervical spondylosis.
- Allow a better understanding of the consequences of cervical spine compression in the brain.
- May be useful for identifying those patients at risk of severe impairment.
- May help the non-invasive assessment of cervical spondylosis, to better predict outcomes and to identify the patients that most likely will benefit from different therapies.

Summary points of cervical spine compression

- Leads to brain atrophy of the sensorimotor cortex, thalami, supplementary motor areas, and a faster rate of cortical thinning and atrophy related to age.
- Causes functional reorganization of the sensorimotor cortex that is more significant for the hand.
- Alters the FC of the brain at the sensorimotor cortex and visual cortex to compensate for the functional loss.
- Leads to white matter demyelination of corticospinal tracts, which extend cranially to the brain cortex mainly at the primary motor area.
- Causes myelin damage at the corpus callosum, mainly at the superior and posterior parietal projection fibers that are related to motor and touch-stimulation.

SCI	spinal cord injury

Introduction

Spasticity is a common complication after spinal cord injury (SCI) that occurs in the context of an upper motor neuron injury syndrome, and may develop even years after the acute injury leading to further loss of function (Harrington & Bockenek, 2011; Rekand, Hagen, & Grønning, 2012).

Spasticity was defined by Lance (1980) as "a motor disorder characterized by a velocity dependent increase in tonic stretch reflexes (muscle tone) with exaggerated tendon jerks, resulting from hyper excitability of the stretch reflex, as one component of the upper motoneuron syndrome." Dynamic phenomena were not included, so the Ability Network (an international panel of clinical experts to develop management algorithms to guide and standardize assessment, treatment and outcomes in SCI people with disabling spasticity) recommends Pandyan definition (Burns et al., 2016): "Disordered sensorimotor control, resulting from an upper motor neuron injury, presenting as intermittent or sustained involuntary activation of muscles."

Considering every SCI people regardless of the time of evolution, neurological level or extent, the prevalence of spasticity is approximately 65% according to the studies of Harrington and Bockenek (2011). Some studies have been conducted on SCI complications; Joseph, Ismail, Naicker, Ying, and Mohammad (2009) demonstrated an incidence of 25%–37% in acute traumatic SCI, New, Rawicki, and Bailey (2002) showed an incidence of 15%–36% in acute nontraumatic SCI, and in papers by Adams and Hicks (2005) or Rekand et al. (2012), incidence of chronic SCI is estimated about 65%–93%. There is no significant correlation among neurological level, ASIA Impairment Scale (AIS) grade, and spasticity, but Adams and Hicks (2005) related severe spasticity with cervical levels and grade A, and a highest prevalence of spasticity among people with grade C.

Pathophysiology of spasticity

The stretch reflex is a monosynaptic reflex that originates in the muscle spindles with any stimulus (not just stretch) and travels through an afferent pathway to the spinal cord (SC) where it synapses with the corresponding alpha motor neuron and contracts the muscle fibers where it is has produced the stimulus. If the stimulus is prolonged, the Golgi tendon organs are activated, and via interneurons Ib, the previous contraction can be relaxed. Studies by Whitlock (1990) show that spasticity is generally due to a lowered threshold of phasic or tonic stretch reflexes; when inhibitory signals are lost due to spinal cord damage, the segmental reflexes are released and become hyperactive. In addition, other spinal mechanisms are postulated, such as fusimotor hyperexcitability, axonal sprouting, reduction of presynaptic inhibition, and reduction of reciprocal inhibition.

Roy and Edgerton (2012) described that clinical features of spasticity depend on the greater or lesser loss of the ability to voluntarily modulate the level of activity of a given motor pool and the capacity of the interneurons that project to these motor pools to recruit the appropriate combination of them.

Diagnosis and Treatment of Spinal Cord Injury. https://doi.org/10.1016/B978-0-12-822498-4.00009-9

Besides, there are plastic alterations in affected muscles. Basically, spasticity causes fibrosis, atrophy of muscle fibers, decrease in the elastic properties, decrease in the number of sarcomeres, accumulation of connective tissue, and alteration of contractile properties toward tonic muscle characteristics.

Manifestations of spasticity in spinal injuries

According to Decq (2003), two classification criteria can be used: the place where the stimulus for spasticity is located, which differentiates between intrinsic if the stimulus emerges within the central nervous system, and extrinsic if the afferences come from other structures such as the skin, muscles, and joints; also if there is no resultant movement, a tonic or static component is described, and if there is any movement, a phasic or dynamic component is described. So, we can distinguish three main types of spasticity:

(a) Intrinsic tonic spasticity: hypertonia.
(b) Intrinsic phasic spasticity: clonus and osteotendinous hyperreflexia.
(c) Extrinsic spasticity: spasms.

The presence of triggers was described by Phadke, Balasubramanian, Ismail, and Boulias (2013); these exacerbating factors can cause a patient with a SCI and a normal or decreased tone to present intense or frequent spasms. The most important triggers are neurogenic bowel (constipation) and bladder problems (hyperreflexia). The supine position is associated with more intense hypertonia and increased likelihood to provoke spasms, and according with Sadeghi, Mclvor, Finlayson, and Sawatzky (2016), the most frequent clinical sign is usually spasms when making any transfer. Other factors such as pregnancy, cold, circadian rhythm, pressure ulcers, menstrual cycle, stress, and even tight clothing also increase spasticity, while acute and severe infections (sepsis) and syringomyelia can cause both an increase of spasticity as a sudden absence of spasticity.

The ability to achieve functional goals may be impaired due to spasticity and can even make the length of hospital stay last longer, according to Richard-Denis, Nguyen, and Mac-Thiong (2020).

Assessment of spasticity and its consequences

Tone measurement

The most widely used method is the Modified Ashworth Scale (Table 1) because, although it is a Likert-type scale and therefore has been criticized for its possible lack of reliability, multiple studies have been carried out and showed that can be considered the most appropriate due to its reliability and test-retest agreement (Baunsgaard, Nissen, Christensen, & Biering-Sørensen, 2016; Meseguer-Henarejos, Sánchez-Meca, López-Pina, & Hernández, 2018). The Tardieu scale is based on the pendulum test and consists of performing the stretching of a muscle between two points and two speeds, but in SCI, it is still considered only as complementary.

Assessment of dynamic phenomena

The frequency and intensity of spasms can be measured using the Penn spasm intensity or frequency scales, but there is a more specific scale for SCI developed by Benz, Hornby, Bode, Scheidt, and Schmit (2005), called the Spinal Cord Assessment Tool Spastic reflexes (SCATS, Table 2).

TABLE 1 Modified Ashworth Scale (Bohannon & Smith, 1987).

0. No increase in tone
1. Slight increase in tone with a catch, or minimal resistance at the end of the range of movement (ROM)
1+. Slight increase in tone with a catch, followed with minimal resistance throughout the remainder (less than half) of the ROM
2. Marked increase in tone through most of the ROM, but limb is easily moved
3. Considerable increase in tone; passive movement difficult
4. Limb rigid or contracted

TABLE 2 Spinal Cord Assessment Tool for Spastic reflexes (SCATS).
Clonus of ankle plantar flexors with rapid passive dorsiflexion of foot
0. No reaction
1. Mild: clonus <3 s
2. Moderate: clonus lasts between 3 and 10 s
3. Severe: clonus >10 s
Flexor spasms in response to pinprick on foot plantar surface with leg and hip in full extension
0. No reaction
1. Mild: extension of great toe or <10 degrees of hip/knee flexion
2. Moderate: 10–30 degrees of hip/knee flexion
3. Severe: >30 degrees of hip/knee flexion
Extensor spasms of quadriceps muscle after extension of leg from a position of hip/knee flexion
0. No reaction
1. Mild: spasms last <3 s
2. Moderate: spasms last between 3 and 10 s
3. Severe: spasms last >10 s

Functional assessment

From the Ability Network (Nene et al., 2018), it is recommended to measure as functional results:

- Joint alterations can be rated by goniometry.
- Interferences of spasticity with activities of daily living are assessed using the Measure of Independence in SCI version III (SCIM III).
- The ability to walk is estimated through Walking Index in SCI scale (WISCI II).
- The impact on the quality of life can also be analyzed, especially with specific scales such as Spinal Cord Injury Spasticity Evaluation Tool (SCI-SET, Table 3) or Patient-Reported Impact of Spasticity Measure (PRISM, Table 4). Generic scales are often not very suitable for SCI, since walking well or performing standing activities are considered signs of a

good quality of life; however, scales such as the SF-36 or the Euro-QOL are still recommended by the Ability Network (Ertzgaard, Nene, Kiekens, & Burns, 2019).

Subjective evaluation

Generally, patients can evaluate their own spasticity with a numerical rating scale, but they can describe their spasticity through specific signs.

Other types of assessment

Ultrasound appearance of spastic muscles can be used, and there are studies (e.g., Hara et al., 2018) that compare the liability of improvement of poststroke spastic muscles treated with botulinum toxin according to its echo intensity (Heckmatt scale), confirming that increased intensity has worse prognostic, since it corresponds to a more chronic and severe spasticity. There is also no useful correlation with neurophysiological parameters.

Treatment of spasticity

Treatment indications

Spasticity may be useful to improve sitting or standing balance, facilitate activities of daily living (ADL) and transfers, maintain muscle mass and venous return. According with Stevenson (2010), treatment is necessary when we find functional disadvantages, and is aimed at preventing joint limitations, reducing pain, facilitating positioning, treating pressure ulcers, hygiene, and facilitating ADLs and transfers.

Modalities of treatment in spinal injury

Since the intensity of spasticity can vary in intensity throughout the same day and eradication treatment is not possible, the management of spasticity should focus on EDUCATION; the patient must learn what spasticity is, its signs and symptoms and its consequences, and how they can be prevented, starting with avoiding exacerbating factors.

(a) **Control of triggers**. The first point in treatment is to eliminate the triggering factors, since although they do not cause spasticity, they are usually present when it appears or worsens.
(b) **Positioning**. The most appropriate posture is sitting; in the wheelchair, the patient must have hips, ankles, and knees flexed at 90 degrees and a slight inclination of the seat, in bed it is recommended lateral decubitus with more forced flexion of the hip and knee of the lower limb located just above the bed. You may improve spasticity using standing devices.
(c) **Physical modalities**. Studies by Gebler (1990) have shown that most of them have a short-lasting effect to be significant, and is based on the maintenance of the myotatic reflex by prolonging a stimulus (stretching, cold) and therefore the stimulation of the Golgi reflex.
   – Stretching. It should be held for at least 1 min to achieve muscle relaxation and increase ranges of motion. It can be done through self-stretching, casting, splinting, or within a physical therapy protocol.
   – Cold or heat application.

- Orthotics and splints. They are used to allow long-term stretching, but they should only be used in moderate spasticity or to maintain outcomes from another previous treatment.
- Muscle-strengthening. In this way, we mitigate the functional repercussions that traction of the antagonist spastic muscle can have on any muscle.
- Electrical stimulation. The repeated application of tetanic contractions by high frequencies >2500 Hz can fatigue the spastic muscle, but this effect is short-lasting, and even long-term may lead to increase spasticity, especially in incomplete injuries. Functional electrical stimulation (FES) is used to strengthen antagonist muscles.
- Robotic systems can work both by causing prolonged stretching and by strengthening antagonists, showed by Alcobendas-Maestro et al. (2012).
- Passive cycling is postulated as a treatment for strengthening weak muscles. In a study by Krause, Szecsi, and Straube (2008), it is shown that there may be improvement in spasticity but the significance is demonstrated with FES compared to passive cycling. The rest of the studies collected in the metaanalysis by Phadke et al. (2019) show that passive cycling can only achieve subjective improvement but objectively there are no effects or there is even a worsening in spasticity.
- Other modalities. Huang et al. (2019) performed a randomized controlled trial on kinesiotaping for spasticity in stroke patients resulting in short-lasting improvement, but there are no trials within SCI people. Shockwaves have been used in poststroke spasticity, and a systematic review by Dymarek et al. (2020) confirms moderate improvement, but it has not been studied in SCI either.

(d) **Oral drugs**. Its characteristics have been studied by Kita and Goodkin (2000), and its specific use for SCI patients has been described by Taricco, Pagliacci, Telaro, and Adone (2006).

- Baclofen. It is considered the gold standard drug because it acts by binding to receptors just in the spinal cord, since it is a structural analog of gamma-amino-butyric acid (GABA, an inhibitory neurotransmitter) and an agonist of GABA-B receptors. In adults, you can start with 15 mg daily in 3 doses and increase every 4–7 days 15 mg daily. Start dosage can be 15 mg/day divided in 3 doses and titration may be 15 mg each 4–7 days; in older patients or with comorbidities, the titration should be slower, and in children, dosage starts with 2.5 mg/day to a maximum dose of 30 mg/day in children 2–7 years and 60 mg/day in children older than 7. Side effects are dose-dependent; the most frequent are fatigue and drowsiness, it can also cause muscle weakness, confusion, dizziness, hypotension, or constipation.
- Diazepam. It binds to GABA-A receptors and causes presynaptic inhibition in the spinal cord. Side effects include sedation and cognitive impairment. Its main indication would be night spasms, prescribing 5 mg daily.
- Clonazepam. It is another benzodiazepine that is typically used when spasms predominate, the starting dose is 0.5 mg daily and requires a slower titration because of its side effects (withdrawal syndrome may be more dangerous).
- Tizanidine. It is an α2 agonist that acts by inhibiting the release of excitatory amino acids in SC interneurons. The most frequent side effects are drowsiness, dizziness, hypotension, or xerostomia, the starting dose is 4 mg daily. The effectiveness of tizanidine, usually considered as a second-line drug, is backed by the largest study.
- Clonidine. It is also an α2 agonist, but it causes hypotension more frequently, so it is not recommended in tetraplegic patients.

(e) **Intrathecal medication**. Studies by McIntyre et al. (2014) and Khurana and Garg (2014) show that baclofen pumps may be considered when high dosages of baclofen are required or there is no response with any other treatment. A programmable pump is implanted into the abdomen, from where a catheter conveys the baclofen into the intrathecal space, usually at the lumbar level since there is greater concentration of GABA receptors in the lumbar spinal cord. Prior to implantation of the pump, all candidates undergo a trial via lumbar puncture, with a dose of 50 μg of baclofen; tone and spasms are measured each 2 h, and if there is positive outcome (spasticity improves), we proceed to gradually withdraw oral drugs and then increase the dose of baclofen in the pump up to the optimum dose (average is 400–500 μg/day), which is kept refilling the reservoir pump at regular intervals (3–6 months). Most adverse effects occur during the titration phase and include drowsiness, headache, nausea, weakness, and hypotension; other complications may be due to mechanical problems (dislodgment, disconnection, kinking, blockage), pump failure, or infection. Any interruption of intrathecal baclofen delivery may result in a severe baclofen withdrawal syndrome that is usually characterized by a sudden increase of spasticity, pruritus, hyperthermia, autonomic dysregulation, seizures, coma, rhabdomyolysis, disseminated intravascular coagulation, and multisystem organ failure.

(f) **Local injections**. They are indicated in focal spasticity. Local phenol injections are discussed in the corresponding chapter. Studies by Palazón-García, Alcobendas-Maestro, Esclarin-Ruz, and Benavente-Valdepeñas (2019) have

shown that focal spasticity is described in some cases of AIS C or D injuries. Botulinum toxin serotype A is produced by the *Clostridium botulinum* bacterium, and is a metalloprotease which, in nerve endings, proteolitically cleaves synaptosomal associated protein (SNAP-25) to inhibit the fusion of the synaptic vesicle with the presynaptic membrane of the axon terminal, and thus ultimately relax the muscle Botulinum toxin can also be used if there are muscles that cause worse functional repercussions (e.g., hip adductors to allow bladder indwelling).

(g) **Surgery**. In SCI, it is not used as an etiological treatment, but it can be applied as a correction of complications (tenotomies and tendon transfers).

(h) **Other treatments**. Studies by Krause and Straube (2003) have reported that repetitive magnetic stimulation at the lumbar nerve roots can decrease lower limbs spasticity in SCI patients, and Korzhova et al. (2018) found that repetitive transcranial magnetic stimulation may be effective against spasticity in SCI patients, even more than against cerebral spasticity.

Outcome measures after treatment

It is performed by means of comparison with previous measurements, the global tolerance to the treatment, and a subjective assessment by the patient. It is also possible to assess the achievement of the objectives set before the treatment, or Patient Global Impression of Change scale, as stated in protocol by Alcobendas-Maestro, Palazón-García, Vargas-Baquero, and Esclarin-Ruz (2015).

Management protocol for spasticity in spinal cord injury

There are studies on the application of one or other treatments such as that of Holtz, Szefer, Noonan, and Mills (2018) but there are no specific protocols or algorithms of management nowadays for spasticity in SCI. Most of the systematic reviews and metaanalysis have been performed on spasticity due to stroke or several mixed pathologies, so no evidence can be shown for any technique for SCI as stated by Taricco et al. (2006) and Khan, Amatya, Bensmail, and Yelnik (2019). A protocol for this treatment is then proposed:

(a) **Positioning and exercise**: The first step is to promote an adequate positioning and educate the patient in the need to exercise daily; during acute in-patient phase, this exercise will be performed in the context of physical therapy, and then in chronic phase perform only mobilizations or stretching as maintenance.

(b) **Control of triggering factors**: It can be considered as the first part of the treatment because it is the first factor to be taken into account when spasticity appears or is decompensated.

(c) **Baclofen**: If spasticity must be treated, the first-line drug is baclofen. We start with a dosage of 15 mg/day divided into 3 doses (lower dosage for children, elderly people or concomitant drugs), and in 3–4 days, it can be increased to 30 mg/day; we must wait 2 weeks to significantly evaluate the effect.
- If the response to treatment is partial, we increase to 45 mg/day and if now the response is complete, the same dosage is maintained.
- If there is no response for 4 weeks, we can go directly to next point by withdrawing baclofen.
- If there is a partial response after 3 weeks with baclofen at 45–60 mg/day and spasticity remains with much functional interference, a second-line drug is added, and this depends on the spasticity features.

(d) **Second-line drugs**:
- Only phasic spasticity. If the only symptom not controlled by baclofen is night spasms diazepam is added in a single nightly dose. If there are spasms or other dynamic phenomena all day long then clonazepam is added.
- Predominance of hypertonia. In general, the drugs preferred as adjuvants to baclofen are tizanidine or clonidine, considering that if the patient has a cervical SCI, we only choose tizanidine.
- Focal spasticity. If there are less than four muscle groups involved in spasticity, botulinum toxin is used. If spasticity is initially generalized but after administration of baclofen or others only focal spasticity persists, botulinum toxin is also indicated.

(e) **Third-line treatment**. If we are using two of the drugs mentioned earlier with a dose close to the maximum allowed or effective, we can add one of the others as third drug (e.g., if we use baclofen and tizanidine, we can associate diazepam). If one of the drugs mentioned earlier cannot be added as a third drug (elderly patients, prevention of adverse events), we can test other drugs with less recognized efficacy or focus on physical modalities (e.g., hydrotherapy).

(f) **Failure of all the treatments**. If we are using three or four oral drugs, we have every exacerbating factor controlled, the patient performs physical activity, and despite everything spasticity is still intense or disabling, we will consider the

intrathecal baclofen pump. We must perform a previous baclofen test dose (positive if instillation of a 50 μg bolus produces improvement of spasticity), there must be permeable intrathecal flow, the patient must be motivated and psychologically stable, and there must have been a minimum time of evolution of the lesion (usually 9–12 months).

Applications to other areas of neuroscience

Differences between spasticity of cerebral and spinal origin (Alcobendas-Maestro et al., 2015; Harrington & Bockenek, 2011).

- The most frequent presentation of spasticity when the origin is spinal is generalized and diffuse, while focal spasticity is more frequent when the origin is cerebral.
- Regarding hypertonia, patients with SCI develop a more intense spasticity, and the clasp knife phenomenon is more frequent.
- The most affected muscles in SCI are extensors (antigravity muscles), especially in the lower extremities, while people with stroke or cerebral palsy show specific synergies (hemiparesis, diparesis) with greater involvement of flexor muscles.
- Regarding intrinsic phasic spasticity, clonus of the plantar flexors is more frequent when the origin is spinal, and patellar clonus is rare if the origin of the spasticity is not cerebral.
- Extrinsic spasticity is more common in SCI; lower limb extensor spasms are the most prevalent spastic sign in SCI. The most important stimulus in SCI is the extension of the hip (especially the last 20 degrees). The highest concentration of mechanoreceptors in people with cerebrovascular diseases is in the knees.
- Spinal spasticity is further exacerbated by visceral diseases.
- SCI patients show shortening of muscles due to prolonged postures, and the most frequent affected muscles are hamstrings that are shortened by keeping the sitting in the wheelchair. However, stroke patients can maintain a posture due to spasticity when they develop spastic dystonia, whose principal example is elbow flexion posture.

Mini-dictionary of terms

Antagonist muscle produces an opposite movement. Since antagonist muscles produce an opposing joint torque to the agonist muscles, this torque can be used to control the motion.
Antigravity muscle acts to counterbalance the pull of gravity and to maintain an upright posture. Most important antigravity muscles are quadriceps femoris and triceps surae.
Catch is a sudden appearance of increased muscle activity as a response to a fast passive stretch, which provokes an abrupt stop.
Clasp knife phenomenon occurs when there is an initial resistance to passive movement of a joint and this tone reduces suddenly and then the limb can move quite freely through its range of motion.
Clonus is an involuntary rhythmic muscle contraction that can cause distal joint oscillation.
Hypertonia is an involuntary increase in muscle resistance to passive stretching.
Osteotendinous hyperreflexia is an exaggerated muscular response to percussion of the tendons.
Spasms are abrupt, involuntary muscle contractions.
Spinal shock is the temporary loss of spinal reflex activity that appears as an initial phase when SCI starts abruptly (as occurs in traumatic or vascular injuries).
Tonus (muscle tone) is a continuous and passive partial contraction of the muscles that works as preparatory for voluntary movement.

Key facts of "diagnosis of spasticity in spinal cord injury"

When a traumatic SCI is starting, the appearance of spasticity means the ending of the spinal shock.
Spasticity cannot be found in lower motoneuron syndromes. The clinical course of cauda equina or conus medullaris syndromes is like a second motoneuron syndrome, and therefore they never develop spasticity.
When the cause of the SCI is vascular, the duration of spinal shock is usually longer.
The presence of neurogenic bladder or bowel is associated with normal or even flaccid tone but frequent and spontaneous spasms.

We must make a differential diagnosis between spasticity and other tone disorders; resistance to passive movement found in extrapyramidal stiffness, paratonia, or simulation is velocity-independent.

Key facts of "treatment of spasticity in spinal cord injury"

Physical modalities are often considered the mainstay of treatment for spasticity, but the duration of the effect is too short, so these treatments are useless. It may be beneficial to strengthen the muscles antagonistic to the spastic ones.
Although there is only one trial with only six SCI patients that compared oral baclofen with placebo, baclofen has been reported to be effective for reducing spasticity (particularly spasms) and is considered the first-line treatment for spasticity.
Since the proportion of elderly SCI patients is increasing, the dosage of baclofen is becoming more difficult due to its effects on cognitive abilities.
Tizanidine is the drug with the most important and reliable studies but it is usually associated with the treatment of stroke spasticity, where it is the only drug allowed.
Clonazepam has not been supported by any published study (not even observational), but it is found in all spasticity treatment protocols when the clinical features are spasms.

Summary points

Spasticity is defined as a disordered sensorimotor control, resulting from an upper motor neuron injury, presenting as intermittent or sustained involuntary activation of muscles. It occurs in 65% of SCI patients.
Spinal cord damage breaks the connection between the brain and the lower areas, so inhibitory signals are not received, and this causes a release and hyperactivity of segmental reflexes.
Spasticity in spinal cord injuries is characterized by being generalized and very intense.
The diagnosis of spasticity is eminently clinical and is made by confirming the clinical symptoms and signs.
The assessment is carried out by means of the measurements of the tone (Modified Ashworth Scale), dynamic phenomena (Spinal Cord Assessment Tool for Spastic reflexes), and of the functional repercussions.
Treatment is required only if the spasticity causes functional disadvantage and the main point is the education of the patient as to the recognition of the factors that can exacerbate the spasticity and the interventions to reduce its intensity.
Baclofen is the first-choice drug for the treatment of spasticity in spinal cord injuries.

Introduction

Falls are a common scenario, among other impairments and conditions, experienced by individuals living with a spinal cord injury (SCI) (see Table 1). Between 31% and 82% of individuals living with SCI will experience at least one fall in a year (Khan et al., 2019). This chapter examines the frequency of falls, circumstances associated with falls, consequences of falls, methods to evaluate fall risk, and intervention programs to manage fall risk.

Fall frequency

Falls are common among people living with SCI who are nonambulatory (use a wheelchair or scooter full time) and those who ambulate. A fall is defined as an event in which an individual unexpectedly makes contact with the ground, floor, or some other lower level (Lamb et al., 2005). Due to differences in functional abilities, it is important to consider differences in fall frequency between those who ambulate and those who do not.

A systematic review and meta-analysis performed by Khan et al. in 2019 found that 34% to 82% of individuals living with SCI who are able to ambulate fell at least once over a 6- to 12-month period, and 31% to 73% of individuals living with SCI who are nonambulatory fell at least once in the same time span (Khan et al., 2019) (see Table 2).

Diagnosis and Treatment of Spinal Cord Injury. https://doi.org/10.1016/B978-0-12-822498-4.00010-5

Osteoporosis

A summary is provided of impairments, conditions, and scenarios commonly associated with spinal cord injury.

TABLE 2 Frequency of falls among ambulatory and nonambulatory individuals living with spinal cord injury (Khan et al., 2019).

Frequency	% of Ambulatory individuals with SCI	% of Nonambulatory individuals with SCI
At least 1 fall	34%–82%	31%–73%
Recurrent falls (more than 1 fall)	28%–68%	30%–41%

The frequency of falls among individuals living with Spinal Cord Injury (SCI) who ambulate and nonambulatory individuals are presented along with data on the frequency of the population, both ambulatory and nonambulatory, that sustain recurrent falls.
(Data source: Khan, A., Pujol, C., Laylor, M., Unic, N., Pakosh, M., Dawe, J., et al. (2019). Falls after spinal cord injury: A systematic review and meta-analysis of incidence proportion and contributing factors. *Spinal Cord, 57*(7), 526–539. https://doi.org/10.1038/s41393-019-0274-4).

Ambulatory individuals are more likely to fall compared to individuals who do not ambulate (Jorgensen et al., 2016). The odds of falling for individuals who ambulate are more than 29 times higher compared to individuals who do not ambulate. Jorgensen et al. proposed that falls are less frequent among nonambulatory individuals due to the larger base of support provided by the wheelchair.

Recurrent falls

Among nonambulatory individuals with SCI, Jorgensen et al. reported that men experienced recurrent falls (more than one fall) 3.1 times more often than women within a year. This finding could be explained by the difference in how men and women manage risk. As age increases, the odds of falling more than once among nonambulatory individuals with SCI decreased. The increased odds of falling among younger adults may be due to activity level and involvement in activities in the workplace that increase exposure to more potential fall situations than older adults (Jorgensen et al., 2016).

Between 30% and 41% of nonambulatory individuals had recurrent falls within a 6- to 12-month period (Khan et al., 2019). Recurrent falls were also reported 14% more often among individuals with greater functional mobility independence, likely because more mobile individuals can engage in more intense physical activity and are therefore more likely to fall (Jorgensen et al., 2016).

Most ambulatory individuals with SCI report falling more than once (Wirz & van Hedel, 2018). Within a 6- to 12-month period, 28%–68% of ambulatory individuals with SCI experienced multiple falls (Khan et al., 2019). Jorgensen et al. reported that individuals who could recover by themselves following a fall experienced 4.7 times more recurrent falls than those who could not get up by themselves. The increased frequency could be related to increased confidence in the ability to recover from a fall among those who are able to recover independently. Increased confidence may result in taking greater risks and exposure to more situations that lead to a fall (Jorgensen et al., 2016).

Fall circumstances

The circumstances in which individuals living with SCI are likely to encounter a fall vary widely. Compared with other populations, including older adults, much less is known about fall risk factors among individuals living with SCI (Khan et al., 2019). Further research is needed to comprehensively understand risk factors associated with falls.

To systematically examine the known risk factors associated with falls, the Biological, Behavioral, Social & Economic, and Environmental (BBSE) Model is used to classify fall risk factors and highlight the multi-factorial nature of falls (Institute of Medicine Committee., 2001). Fig. 1 displays a visual representation of the BBSE.

Biological risk factors

Biological contributors of falls among both ambulatory and nonambulatory individuals living with SCI include many factors. The most common contributors include muscle weakness, loss of balance, spasticity, and muscle spasms (Brotherton, Krause, & Nietert, 2007b; Jorgensen et al., 2016; Musselman, Arnold, Pujol, Lynd, & Oosman, 2018; Nelson et al., 2010). Lower levels of functional mobility have also been linked to an increased risk of falling (Wannapakhe, Arayawichanon, Saengsuwan, & Amatachaya, 2014). However, Nelson et al. found that persons with more function are also at greater risk because they have a greater exposure to situations where falls may occur, making them more likely to engage in risk-taking behaviors (Nelson et al., 2010). Other biological factors that may increase the risk of falls summarized by Khan et al. include: male sex (wheelchair users only), an increased number of comorbidities, trunk weakness, fatigue, walking asymmetry, shorter duration since sustaining SCI, narcolepsy, and reduced sensation (Khan et al., 2019). Age can also be a risk factor. Among 94 participants, individuals who reported a high frequency of falls were significantly younger. This may be because these individuals are more active and have greater levels of enthusiasm and energy (Amatachaya, Pramodhyakul, Wattanapan, & Eungpinichpong, 2015). In addition, reports of pain in the 2 months prior to the fall can affect the performance of activities of daily living and increase fall risk (Nelson et al., 2010). Studies have also revealed that individuals living with incomplete spinal cord injury, injuries in which partial sensation and/or motor function persists below the level of injury, experience significantly more falls than individuals with complete injuries (Amatachaya, Wannapakhe, Arrayawichanon, Siritarathiwat, & Wattanapun, 2011).

Behavioral risk factors

In a systematic review and meta-analysis, Khan et al. found that the most commonly reported behavioral attributions associated with falls included inattention or distraction, ambulation, fear of falling, a history of previous falls, and not using the safety features of a wheelchair or walking aid (Khan et al., 2019). Risk-taking behaviors are also associated with falls (Jannings, 2017), which is theorized to be the reason why men are three times more likely to fall than women (Jorgensen et al., 2016). Nelson et al. also found alcohol abuse increased the risk of falls as well as the use of a shorter

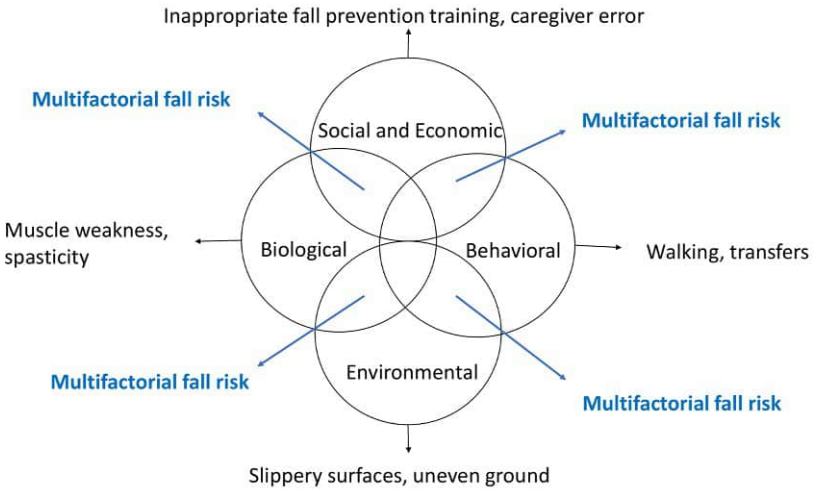

FIG. 1 Biological, Behavioral, Social and Economic, and Environmental Fall Model. The figure provides a visual representation of the biological, behavioral, social and economic, and environmental fall model. The model provides a framework for the classification of circumstances associated with falls. Please note how the various components intersect. This represents the multi-factorial nature of falls and the need to consider various factors when designing programs to manage fall risk. *(Data source: Institute of Medicine (US) Committee on Health and Behavior: Research. (2001). The National Academies Collection: Reports funded by National Institutes of Health. In Health and behavior: The interplay of biological, behavioral, and societal influences. National Academies Press (US) Copyright © 2001, National Academy of Sciences. https://doi.org/10.17226/9838).*

wheelchair. A shorter wheelchair allows for greater maneuverability; however, the design makes the chair less stable overall (Nelson et al., 2010). Finally, individuals with a lower quality of life were found to fall more frequently (Jorgensen et al., 2016).

Environmental risk factors

Environmental contributors to falls exist both within and outside the home. Hazards such as railings, stairs, heavy doors, and slippery floors are identified as increasing the risk of falls (Jorgensen et al., 2016). Among nonambulatory individuals, Sung et al. reported that the bathroom was the most common location for falls to occur, and 43% of falls were associated with pushing or driving the wheelchair on rough surfaces (Sung, Trace, Peterson, Sosnoff, & Rice, 2019). Forslund et al. found that 65% of falls occurred indoors, and 47% of falls occurred between the hours of 9 AM and 6 PM (Forslund et al., 2017).

Social and economic

Social and economic factors were also identified as fall contributors. Nelson et al. found that a higher level of education was associated with falls (Nelson et al., 2003). In addition, lack of fall prevention training (Musselman et al., 2018) and caregiver error (Jannings, 2017) were also found to contribute to falls. Table 3 summarizes fall risk factors according to the BBSE.

Consequences of falls

Falls experienced by individuals living with SCI can result in a variety of physical and psychosocial consequences for the faller, as well as high costs to society at large (see Table 4).

Physical consequences of falls

A systematic review and meta-analysis conducted by Khan et al. (2019) revealed that the frequency of reported falls which resulted in injuries ranged from 6% to 62% in ambulatory individuals with SCI and 13%–38% in nonambulatory individuals with SCI, though the frequency of total falls experienced (both injurious and noninjurious) appears to be similar between ambulatory and nonambulatory individuals with SCI (see Table 5).

While the majority of physical injuries sustained as a result of a fall were considered minor, such as bruises, cuts, or abrasions, approximately 15% of falls result in more severe injury, such as bone fractures (Amatachaya et al., 2011; Brotherton, Krause, & Nietert, 2007a), loss of consciousness (Wannapakhe et al., 2014; Wannapakhe, Arrayawichanon, Saengsuwan, & Amatachaya, 2015), or concussion (Forslund et al., 2017). Other moderate injuries reported as a result

TABLE 3 The top risk factors for falls classified by the biological, behavior, social and economic, and environmental model found in a systematic review and meta-analysis by Khan et al. (2019).

Biological	Behavioral	Environmental	Social and economic factors
• Muscle weakness • Impaired balance • Greater function/ mobility • Muscle spasms/ spasticity • Lower function/ mobility	• Inattention/distraction during movement • Ambulating • Fear of falling • Previous History of Falls • Not using protective straps/safety belt/ wheel locks	• Hazards in environment • Obstacles • Stairs • Uneven ground • Doors	• Higher education levels • Lack of fall prevention training • Caregiver error

The top risk factors for falls, organized using the biological, behavioral, social & economic, and environmental model, as reported by Khan et al. in a 2019 systematic review.

TABLE 5 Injuries reported among fallers living with SCI (Khan et al., 2019).

Population	Frequency of injuries
Ambulatory individuals	6%–62%
Nonambulatory individuals	13%–38%

A summary is reported of the injuries experienced by individuals living with spinal cord injury, as reported by Khan et al. in a 2019 systematic literature review and meta-analysis. Note the increased reports of injuries among ambulatory individuals.

of a fall sometimes include muscle tears (Amatachaya et al., 2015), sprains, bloody nose, and numbness (Nelson et al., 2010). In severe cases, injuries sustained from a fall can even result in death (Nelson et al., 2010).

Ambulatory individuals with SCI experience a greater number of minor injuries as a result of a fall compared to nonambulatory individuals (Wannapakhe et al., 2015). They also have a greater incidence of fractures as a result of falls compared to healthy older adults (Brotherton et al., 2007a). Ambulatory women with SCI report more injurious falls than men of the same population, similarly to women without SCI compared to their male peers. Ambulatory individuals with SCI who have a history of recurrent falls are also at an increased risk of experiencing an injurious fall compared to those with no such history (Jorgensen et al., 2017).

Psychosocial consequences of falls

Fear of falling

While physical consequences of falling are more easily identified, there also exist psychosocial consequences of falls that heavily influence individuals with SCI.

Many individuals living with SCI who experience a fall, report an increase in fear of falling (Amatachaya et al., 2015; Musselman et al., 2018). Fear of falling (FOF) is defined as an ongoing concern about experiencing a fall which may ultimately limit the performance of daily activities (Legters, 2002). Developing a FOF is a common occurrence after experiencing a fall; however, a FOF can develop even when there is no history of falls. While a moderate amount of FOF may prompt individuals to be more mindful of their environment when performing tasks, FOF often leads individuals to unnecessarily avoid performing activities which they are physically capable of doing (Tinetti, Speechley, & Ginter, 1988). This can result in the deconditioning of the body which may put individuals with SCI at a further increased risk of falling and experiencing more severe consequences of falls when activity by necessity occurs, such as reaching for

an item while getting dressed or transferring to a toilet (Brotherton et al., 2007b). Fear of falling may be caused by post-fall–related experiences, such as injury, or underlying factors that enhance fall risk, such as having poor balance, muscle weakness, and impaired sensation, which may decrease fall-related self-efficacy (Jorgensen et al., 2017).

Fear of falling is also a risk factor for recurrent falls in ambulatory individuals with SCI (Phonthee, Saengsuwan, Siritaratiwat, & Amatachaya, 2013) and has been found to be associated with decreased community participation (Peterson, Cho, & Finlayson, 2007; Tinetti, Speechley, & Ginter, 1988) and lower quality of life (Nelson et al., 2010). Sung et al. found that 65% of nonambulatory individuals with SCI reported a fear of falling. Of those who reported a FOF, 26% also indicated that they limited their activities because of this fear (Sung, Peterson, Shen, Sosnoff & Rice, 2021). Friedman, Munoz, West, Rubin, and Fried (2002) found that there was a "spiraling effect" between increasing fall occurrences, FOF, and functional decline. Ambulatory individuals with SCI who have better balance appear to show less fear of falling (Wirz, Müller, & Bastiaenen, 2010), suggesting that interventions targeted at improving balance may help to decrease FOF.

Negative feelings and decreased community participation

In combination with increased fear of falling, other feelings expressed by individuals with SCI after falling include feelings of embarrassment (Jannings, 2017) and frustration (Musselman et al., 2018), even if they were not physically injured. While these emotions, combined with FOF, may motivate an individual to be more cautious in the future, of great concern is the frequently reported decrease in community participation and social interactions by as many as 45% of fallers with SCI (Musselman et al., 2018).

Societal consequences of falls

In addition to the physical and psychosocial burden of falls, there also exists a significant societal burden. In 2010, among U.S. adults, it was estimated that fall-related injuries cost health-care systems 111 billion dollars (Verma et al., 2016). Saunders, DiPiro, Krause, Brotherton, and Kraft (2013) found that approximately 20% of falls experienced by ambulatory individuals with SCI resulted in the need for medical attention. Fall-related injuries can also lead to an increased dependence on others for assistance with daily activities. This can lead to increased caregiver burden and costs over a lifetime (Forslund et al., 2017).

Assessment of fall risk

The assessment of fall risk among people living with SCI is of high importance to foster management of fall risk. Methods used to assess fall risk include clinical measures (Srisim, Saengsuwan, & Amatachaya, 2015), self-report strategy (Sung et al., 2019), and photo-elicitation techniques (Singh et al., 2020).

It is important to note that fall risk factors in people with SCI have shown to be specific, individualized, and highly dependent on the specific characteristics of the injury including the type of injury (complete or incomplete), chronicity of injury, and the level of injury. Other factors, such as the functional ability of the person with SCI, including personal characteristics and the surrounding environment, also determine the level of risk of falls. Therefore, fall risk assessments differ between ambulatory and nonambulatory people with SCI (see Fig. 2).

Assessment among ambulatory people with SCI

Most studies on fall risk assessment have focused on individuals living with SCI who ambulate (Abou, de Freitas, Palandi, & Ilha, 2018). Previous research indicates that biological factors are the primary risk factors associated with falls among ambulatory people and include level of functional independence, physical fitness, gait velocity, reaction time, limits of stability, and lower extremity muscle strength (Abou et al., 2018). These biological factors are measurable in clinical settings through the performance of clinical measures including the Berg Balance Scale (BBS), the Spinal cord Independence Measure (SCIM) III, and the Timed Up and Go (TUG). Abou, Ilha, Romanini, and Rice (2019) reported that the BBS is the most appropriate clinical balance measure and has the ability to effectively predict future falls among ambulatory people with SCI. However, since falls are multi-factorial, there is no consensus on the relationship between level of mobility and fall risk in this population. Some studies reported a significant relationship between a higher level of mobility and increased risk of falling (Amatachaya et al., 2018; Phonthee, Saengsuwan, & Amatachaya, 2013), while other studies related lower level of mobility to an increased risk of falling (Srisim et al., 2015). Undoubtedly, other biological factors such as sex, type

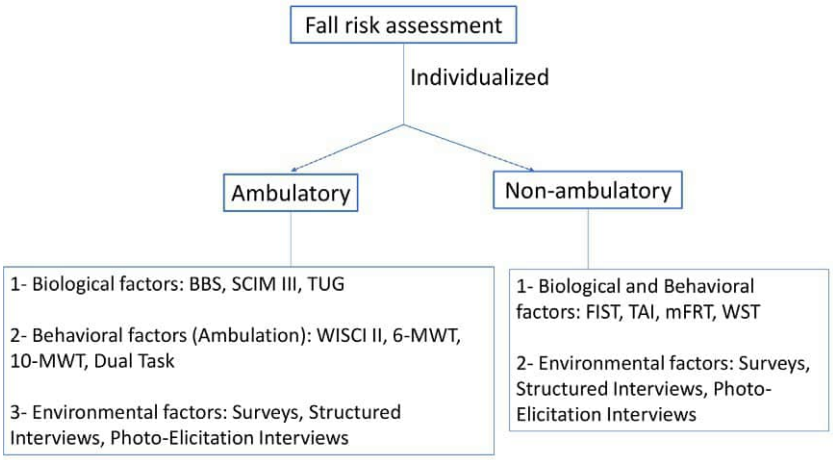

FIG. 2 Summary of fall risk assessments among people living with spinal cord injury. This table depicts the various assessments to examine fall risk among individuals living with spinal cord injury categorized by the primary target area using the biological, behavioral, social and economic, and environmental model. Abbreviations: *6-MWT*: 6-minute walking test, *10-MWT*: 10-meter walking test, *BBS*: Berg balance scale, *FIST*: function in sitting test, *mFRT*: modified functional reach test, *SCIM III*: spinal cord independence measure III, *TUG*: timed up and go, *WISCI II*: Walking Index for SCI*TAI*: transfer assessment instrument, *WST*: Wheelchair Skills Test.

of injury, fatigue, pain, sensorial impairment, time since SCI, trunk weakness, and the presence of comorbidities also contribute to an increased risk of falling.

Ambulating itself has been reported as one of the most common behavioral risks of falling along with inattention or distraction (Khan et al., 2019). This is because ambulating may easily lead to a loss of balance when performing an additional task (i.e., ambulation and a cognitive task) (Amatachaya et al., 2018). In clinical settings, ambulation can be assessed by use of the Walking Index for SCI (WISCI-II), the 6-Minute Walking Test (6-MWT), dual-task obstacle crossing (Amatachaya et al., 2018), and the 10-Meter Walking Test (10-MWT) (Moore et al., 2018). Amatachaya et al. showed that failing to cross an obstacle while performing a color-word Stroop task during the 10-MWT and the TUG is significantly associated with future risk of falls (Amatachaya, Promkeaw, Arayawichanon, Thaweewannakij, & Amatachaya, 2020). However, the relationship between ambulation outcome measures and falls still need to be further explored. Other behavioral factors that increase the risk of falling including a fear of falling, a history of previous falls, and not using a walking aid should be assessed with ambulation (Khan et al., 2019).

Environmental factors that increase the risk of falling both within and outside of the home can be assessed using different techniques. Hazards in the environment such as stairs, ramps or hills, and uneven or slippery surfaces can be assessed using surveys, semistructured interviews, and photo-elicitation interviews (PEI) (Brotherton et al., 2007a; Musselman et al., 2018). The Craig Hospital Inventory of Environmental Factors (CHIEF) is a comprehensive measure to evaluate environmental barriers (Whiteneck et al., 2004). However, compared with surveys and semistructured interviews, PEI provides more details about the environmental factors related to falls. PEI allows participants to take photographs of situations, places, people, hazards in the environment, and obstacles that may lead them to falls. Also, through PEI, participants are actively involved in identifying factors that lead them to falls (Clark-IbáÑez, 2004).

Finally, social and economic fall risk factors should also be considered and need further exploration among ambulatory people with SCI through surveys and interviews. Among other populations, including older adults, the level of education, fall prevention training, caregiver and family training have been associated with falls (Deandrea et al., 2010). These factors should be taken into consideration when evaluating an individual's risk for falls.

Assessment among nonambulatory people with SCI

Few studies have focused on the exploration of fall risk factors among nonambulatory people with SCI (Sung et al., 2019). Performance of activities of daily living constitutes the main behavioral fall risk in this population. The influence of muscle spasticity and poor balance can negatively affect the safe performance of activities of daily living while using a wheelchair (Abou et al., 2018). Activities of daily living including transfers from/to different surfaces, wheelchair propulsion, and reaching for an object are commonly associated with falls (Sung et al., 2019) can be assessed with clinical measures. The Function in Sitting Test (FIST) (Abou, Sung, et al., 2019), Wheelchair Skills Test (Keeler, Kirby, Parker, McLean, & Hayden, 2019), Transfer Assessment Instrument (TAI) (Worobey, Rigot, Hogaboom, Venus, & Boninger, 2018; Worobey, Zigler, et al., 2018), and modified Functional Reach Test (Lynch, Leahy, & Barker, 1998) can be used

to assess sitting balance, wheelchair skills, transfers, and functional reach, respectively, among nonambulatory people with SCI. Additionally, a smartphone-based assessment has been recently developed to assess sitting balance among nonambulatory people with SCI (Frechette, Abou, Rice, & Sosnoff, 2020). However, the relationship between the aforementioned outcome measures and falls still needs to be established.

Similar to ambulatory people with SCI, environmental factors that constitute important fall risk factors among nonambulatory people with SCI can be assessed using surveys, semistructured interviews, and PEI (Brotherton et al., 2007a; Musselman et al., 2018). PEI may foster the identification of environmental factors associated with falls in the bathroom, street, bedroom, living room, and kitchen. In addition, PEI may provide clinicians with more details about environmental conditions including wet and slippery surfaces, low lighting, and uneven ground which were also reported as conditions that increase the risk of falling among nonambulatory people with SCI (Sung et al., 2019).

Assessing fear of falling

Several approaches have been used by researchers to assess FOF in individuals with SCI. While some studies have utilized single-item questions, such as directly asking participants if they are worried or concerned about falling (Jorgensen et al., 2017; Sung et al., 2019), others have used more comprehensive assessment tools to identify levels of concern about falling in relation to specific activities. The Falls Efficacy Scale-International (FES-I) (Yardley, Beyer, Hauer, Kempen, & Piot-Ziegler, 2005) was designed for ambulatory elderly individuals but has been used in studies of other ambulatory individuals including those with SCI (Wirz et al., 2010). Boswell-Ruys, Harvey, Delbaere, and Lord (2010) modified the FES-I to be more appropriate to assess FOF among nonambulatory individuals with SCI, creating the Spinal Cord Injury-Fall Concerns Scale (SCI-FCS). Assessment tools such as the FES-I and SCI-FCS allow for a more comprehensive understanding of FOF and can help in the creation of tailored interventions to address warranted and unwarranted FOF.

Intervention program to manage fall risk

As a result of the high frequency and significant consequences associated with falls among individuals living with SCI, effective management of fall risk is critical for the health and well-being of individuals living with SCI.

Rice, Sung, Keane, Peterson, and Sosnoff (2019) examined the efficacy of a one-time, 1:1, 45-min intervention among 18 full-time manual wheelchair users living with SCI. The intervention focused on the refinement of transfer skills and implementation of an exercise program to improve upper extremity strength and core stability. After the initial education, participants were given an opportunity to practice the skills and discuss individual fall concerns. Participants were then asked to integrate the education at home for a period of 12 weeks. After exposure to the intervention, fall incidence significantly decreased and seated balance significantly improved. Improvements were also seen with regards to quality of life.

Amatachaya et al. (2020) examined the effects of walking training on a walking track with different surfaces, including grass, soft areas, and pebbles, compared to standard overground walking training among individuals living with SCI who ambulate independently, with or without an assistive device. Participants engaged in walking training on the walking track (intervention) or received standard overground walking training (control) 5 days per week, 30 min per day for 4 weeks. In both groups, participants walked at a self-selected speed. Six months after exposure to the intervention fewer participants in the intervention group ($n = 5$, 18%) experienced falls compared to the control group ($n = 12$, 46%).

While the literature is sparse related to specific fall management programs for individuals living with SCI, other peer-reviewed intervention programs have been developed to manage common circumstances associated with falls. The studies presented in Table 6 contain details on intervention programs that target risk factors associated with falls including poor transfer skills (Worobey, Rigot, et al., 2018; Worobey, Zigler, et al., 2018), wheelchair and scooter skills (Keeler et al., 2019), and dynamic balance (Chisholm et al., 2017; Khurana et al., 2017; Qi et al., 2018; Williams et al., 2020).

Application to other areas of neuroscience

In this chapter, we have examined falls among individuals living with SCI. This is an expanding topic of concern that frequently impacts other individuals living with a variety of neurological impairments. For example, falls are also very common among individuals living with Multiple Sclerosis and can result in similarly significant consequences.

When assessing which individuals are at high risk for falls and circumstances associated with falls, it is important to consider that falls are multi-factorial. While some of the information presented in this book chapter can be carried over to other populations of individuals living with neurological impairments, it is important to note the various factors that

TABLE 6 **Intervention programs to manage fall risk among ambulatory and nonambulatory individuals living with spinal cord injury.**

Author	Area of focus	Population	Key intervention components	Outcome
Rice (Rice et al., 2019)	Comprehensive fall management	Full-time manual wheelchair users	Transfer education and exercise to increase upper extremity strength and core stability	After exposure to the intervention: Decreased fall frequency and improved seated balance
Amatachaya (Amatachaya et al., 2020)	Comprehensive fall management	Independent ambulators or individuals who used an assistive device to ambulate	Walking on a track with different surfaces (grass, soft areas, pebbles) vs standard overground walking training	18% of intervention participants experienced a fall vs control group
Worobey (Worobey, Rigot, et al., 2018; Worobey, Zigler, et al., 2018)	Transfer skills	Individuals who perform a sitting pivot transfer	In-person management of individual transfer skill deficits vs online skill management	Improvement seen in transfer quality through both in-person and online education
Keeler (Keeler et al., 2019)	Wheelchair skills	Full-time manual and power wheelchair users	Various instruction methods (1:1, group, peer-led, etc.) to improve wheelchair skill capacity and quality	Various formats studied result in improvements in wheelchair skill capacity and quality among manual and power wheelchair users
Williams (Williams et al., 2020)	Dynamic balance	C6-T12, AIS A-C	Arm crank ergometer training	After exposure to intervention, static sitting balance significantly improved
Qi (Qi et al., 2018)	Balance control and quality of life	C6-L1, AIS B-D	Tai Chi	Individuals who practiced Tai Chi had greater static sitting balance and increased quality of life compared to a control group
Khurana (Khurana, Walia, & Noohu, 2017)	Dynamic balance	T6-T12	Virtual reality game training	Virtual reality game-based training resulted in greater improvements in balance and functional performance compared to real-world, task-specific training
Chisholm (Chisholm, Alamro, Williams, & Lam, 2017)	Dynamic balance	C7-T4, AIS A-B	Robotic training	Overground robotic training resulted in improved postural stability vs treadmill-based robotic gait training

A summary is provided of peer-reviewed intervention programs designed to comprehensively manage fall risk and target risk factors associated with falls. References of individual studies are noted within the table.

influence falls. For example, wheelchair propulsion or driving over rough surfaces is reported as a common circumstance associated with falls among individuals living with SCI. This information will apply to other populations who use wheelchairs and scooters on a full-time basis. However, other factors more specific to SCI, such as the influence of spasticity or lack of sensation, may further increase the individuals' risk of falling. As a result, it is important for a clinician to consider the various factors that influence falls when examining fall risk and developing intervention programs to manage fall risk.

Among both individuals living with SCI and other neurological impairments, research related to this topic is limited. In recent years, research has begun to uncover important points including the frequency of falls and circumstances associated with falls. However, compared to research focused on older adults, the literature is very limited. Most significantly there is limited information regarding appropriate ways to assess fall risk and interventions to manage falls among individuals living with SCI and other populations affected by neurological impairments. It is important to consider that this is an evolving field of study and further research is needed.

Mini-dictionary of terms

Ambulatory: A term referring to individuals who are able to walk by themselves with or without an assistive device, such as a cane or walker.

Balance: A generic term describing the dynamics of body posture to prevent falling. Balance refers to the ability of the body to maintain the center of gravity within the limits of stability as determined by the base of support.

Deconditioning: A decline in the function of body parts and systems as a result of inactivity or lack of use.

Dual-task: A paradigm in experimental neuropsychology that requires an individual to perform two tasks simultaneously. A common dual-task example used in clinical experiments consists of walking and carrying on a conversation.

Fall: An event in which an individual unintentionally makes contact with some lower surface, such as the ground or floor.

Fear of falling: A fear or concern that a fall will occur. Fear of falling may develop as a result of a fall or independent of a fall event. An individual may limit their performance of activities they enjoy doing in their home or community that they remain capable to doing.

Gait training: Strategy to improve ambulation skills focused on restoring the pattern of walking to develop biomechanically efficient gait. Assistive devices may be used.

Nonambulatory: A term referring to individuals who are unable to walk without assistance from another person or a mobile device, such as a wheelchair.

Photo-Elicitation Interviews: An interview strategy in which participants are asked to take photos of areas associated with falls in order to foster a more in-depth discussion.

Quality of life: The degree to which an individual is healthy, comfortable, and able to participate in and enjoy life. This can be challenging to assess because nearly everyone places different values on these measures.

Key facts of fall frequency and fall circumstances

- Falls are a common health concern for individuals living with SCI.
- Between 31% and 82% of individuals living with SCI will experience at least one fall over a 6- to 12-month period of time.
- Individuals who ambulate fall more often compared to individuals who use a wheelchair or scooter.
- A wide variety of factors, such as muscle weakness, being distracted, and pushing or driving a wheelchair on a rough surface contribute to the occurrence of a fall.
- Falls often occur due to a combination of many different factors. For example, a fall may occur as a result of pushing a wheelchair on a rough surface while talking with a friend (being distracted).

Key facts of consequences of falls

- Falls may result in physical injuries and have psychosocial consequences, as well as societal costs.
- Up to 62% of individuals living with SCI may experience an injury as a result of a fall.
- The majority of physical injuries are minor; however, significant injuries, such as fractures or concussions, may occur.
- Fear of falling can lead to a spiraling effect, in which someone who is afraid of falling stops performing activities, leading to deconditioning, which in turn puts them at greater risk of falling in the future.

Summary points

- This chapter examines fall frequency, consequences of falls, fall circumstances, methods to assess fall risk, and interventions to manage fall risk.

- In a 6- to 12-month period, 34%–82% of ambulatory individuals and 31%–73% of nonambulatory individuals living with SCI experience at least one fall.
- Between 28% and 68% of ambulatory and 30% and 41% of nonambulatory individuals will experience recurrent falls.
- The circumstances associated with falls among ambulatory and nonambulatory individuals are diverse; however, some of the most common circumstances include falls due to the influence of muscle weakness or spasticity and inattention or distraction.
- Falls may occur both inside and outside of the home and were more common among individuals who were working or studying.
- Falls can result in significant consequences, including physical injuries, such as bruising, fractures, or head injuries.
- Falls can also result in the development of a fear of falling that can limit engagement in desired activities in the home and community.
- Falls can be evaluated using a combination of clinical assessments, self-report surveys, or photo-elicitation interviews.
- Interventions to manage fall risk show promise; however, additional studies are needed to develop comprehensive intervention programs.

List of abbreviations

ARDS	acute respiratory distress syndrome
bDMARDs	biological disease-modifying anti-rheumatic drugs
CT	computerized tomography
Covid-19	coronavirus disease 2019
GCs	glucocorticoids
HPA	hypothalamic-pituitary-adrenal
IUC	indwelling urethral catheter
ICU	intensive care unit
ISNCSCI	International Standards for Neurological Classification of the Spinal Cord Injury
JAKi	Janus kinase inhibitors
MRI	magnetic resonance imaging
NICE	National Institute for Clinical Excellence
NE	norepinephrine
PI	pulmonary infections
PEP	positive expiratory pressure
PPE	personal protective equipment
ISC	self-catheterization
SARS-CoV-2	severe acute respiratory syndrome coronavirus 2
SPC	suprapubic catheter
SCI	spinal cord injury
SCIP	spinal cord-injured patients
SNS	sympathetic nervous system
SPNs	sympathetic preganglionic neurons
UTI	urinary tract infections
WHO	World Health Organization

Introduction

An epidemic of severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) started in Wuhan in December 2019 and quickly spread across the world. The 2019 coronavirus disease (Covid-19) was declared a pandemic on March 11, 2020, by the World Health Organization (WHO). On February 7th, 2021, 105,962,538 cases were confirmed worldwide with 2,313,136 deaths (Johns Hopkins Coronavirus Resource Center, 2020). This new SARS-CoV-2 has brought higher levels

Diagnosis and Treatment of Spinal Cord Injury. https://doi.org/10.1016/B978-0-12-822498-4.00011-7

of illness, deaths, and fear to our planet than any other virus in current history. In this context, it is mandatory to determine the effect in people with spinal cord injury (SCI).

SCI induces numerous chronic disorders that put these individuals at a high risk of severe Covid-19 prognosis. Specifically, the SCI population presents higher rates of hypertension, SCI-induced immunosuppression, and, if the metameric level is T8 or above, respiratory failure with continuous or episodic hypoxemia due to respiratory muscle weakness. Sympathetic denervation following SCI compromises body temperature regulation, as a result of dysautonomia, which not only complicates the early diagnosis of Covid-19 which places them at risk of a poor prognosis, but also makes it difficult to control infection transmission to other patients and/or healthcare staff.

In general population, clinical symptoms appear after an incubation period of around 5 days (Zhu et al., 2020), presented in order of frequency as: fever (87.9%), dry cough (67.7%), asthenia (38.1%), dyspnea (18.6%), pharyngeal pain and odynophagia (13.9%), headache (13.6%), arthromyalgia (14.8%), chills (11.4%), nausea or vomiting (5%), nasal congestion (4.8%), and anosmia and diarrhea (3.7%). Approximately 80% of patients present as asymptomatic or with few symptoms including dry cough and fever or low-grade fever (Guan et al., 2020), but the remaining 20% of cases develop around the 7th day after the onset, severe hypoxemic respiratory failure that progresses to Acute Respiratory Distress Syndrome (ARDS) (15% of the total) and even to multi-organ failure (5% of the total), requiring mechanical ventilation and admission to an Intensive Care Unit (ICU) (Huang et al., 2020). Up to 18% of patients who request consultation for Covid-19 compatible symptoms do not present radiological alterations. When these appear, the most frequent clinical sign is unilateral or bilateral ground glass opacification with an interstitial pneumonia pattern or bilateral patched consolidation, evident on plain radiography and on chest computerized tomography (CT) examination (56.4%) (Hosseiny et al., 2020; Zu et al., 2020). At diagnosis, more than 80% of patients present lymphopenia (Guan et al., 2020), which is more severe and accompanied by neutrophilia in patients requiring ICU admission (Huang et al., 2020). The main cause of death after Covid-19 infection is respiratory failure and fulminant myocarditis, (Ruan et al., 2020). In these patients, a highly exaggerated inflammatory response has been described known as hyperinflammatory syndrome, with a massive release of cytokines into the bloodstream (Mehta et al., 2020; Ritchie & Singanayagam, 2020) similar to that observed in hemophagocytic syndromes caused by other virosis (Ramos-Casals et al., 2014). A series of clinical factors have been described, associated with symptoms of greater morbidity and mortality: male gender, age above 60 years—especially above 80 years old, where the fatality rate is close to 16%—and the presence of previous comorbidities such as: hypertension, ischemic heart disease, diabetes mellitus, lung disease, and various disease entities that lead to immunosuppression, such as autoimmune diseases or cancer (Zhou et al., 2020). Analytical markers associated with a higher risk of mortality are sustained lymphopenia and elevation of D-dimer, IL-6, ferritin, LDH, and troponin (Zhou et al., 2020).

The aim of this chapter is to analyze the clinical presentation of Covid-19 in spinal cord-injured patients (SCIP). The authors pretend to make pause to understand if this emergent disease, which is deadly hitting our general population, behaves in the same or different way as in these especial patients, in order to understand if the SCI condition is acting as a risk factor for morbidity or not, and why. For this purpose, we believe the immune system plays a significant role in infection, especially from our knowledge of other infections.

Immunosuppression due to spinal cord injury

Among non-specialist the most evident consequences of SCI is loss of mobility and sensibility. However, in spite of their dramatic effect on patient quality of life, this is only the tip of an iceberg compared to the other lifelong neurological and non-neurological sequelae. These patients have an immunodepressed state characterized by changes in the number and function of immune cells that render them highly susceptible to infections (Bracchi-Ricard et al., 2016; Brommer et al., 2016; Kopp et al., 2017). Indeed, these are the leading cause of morbidity and mortality after SCI (Thietje et al., 2011). In this chapter, we review why immunodepression occurs after SCI and how this affects the ability of patients to cope with the current Covid-19 pandemic and other infectious diseases.

Pathophysiology of spinal cord injury-induced immunodepression

The physiological responses to physical or psychological stress are mediated by the coordinated response of the sympathetic nervous system (SNS) and the hypothalamic-pituitary-adrenal (HPA) axis. Both systems mediate the so-called fly-or-fight responses by setting the whole organism to cope with stressful stimuli at the expenses of arresting functions that are not indispensable for immediate survival. This physiological and evolutionary adapted response may, however, turn into a maladaptive chronic situation. Spinal cord injuries are a source of tremendous physical and psychological stress that unfortunately exemplifies the effect on the immune system of maladaptive SNS and HPA responses.

Dysregulation of the sympathetic nervous system

The main mechanism driving immunodepression after SCI is the dysregulation of the autonomic sympathetic nervous system. The cell bodies of the sympathetic preganglionic neurons (SPNs) are localized in the lateral horn of the spinal cord, in the intermedio-lateral nucleus. Classically, it has been considered as sympathetic the neurons located from T1 to the first lumbar segments (L2 – 3), although recently, the parasympathetic neurons located in the lateral horn of the sacral segments have been shown to have phenotypical and ontogenetic characteristics of SPNs (Espinosa-Medina et al., 2016). In any case, SPNs synapse in sympathetic ganglia majorly with post-ganglionic noradrenergic neurons, which in turn release norepinephrine (NE) in the target organs, though a minority of post-ganglionic sympathetic neurons are cholinergic, as those innervating sweat glands (Dale & Feldberg, 1934). The timing and intensity of SPNs activation is controlled by nuclei located in the brainstem, pons and hypothalamus that project inhibitory descendants into the spinal cord (Dénes et al., 2005). After a severe SCI, these supraspinal projections are interrupted and, thus, SPNs loss their inhibitory inputs. Consequently, when these neurons are activated, it may give raise to an exaggerated or more durable sympathetic response and, thus, to an excessive release of NA in the target organs. In addition, the sublesional spinal circuitry involved in the control of preganglionic neurons undergoes a remodeling process that favors the connectivity between activating interneurons and SPNs (Ueno et al., 2016). Overall, the resultant sympathetic overactivation below the lesion level underlies a plethora of autonomic dysfunctions after SCI, including the suppression of the immune system.

The sympathetic nervous system innervates both the primary and the secondary lymphoid organs, and modulates all the immune processes, from hematopoiesis to immune responses (Jung et al., 2017; Noble, Brennan, & Popovich, 2018). Immune cells sense NE majorly through beta-2-adrenergic receptors, although monocytes/macrophages also express lower levels of alpha-1- and alpha-2-adrenergic receptors (Kavelaars, 2002). The overall effect of adrenergic receptor activation on physiological conditions over innate immune cells is anti-inflammatory (Meltzer et al., 2004; Nance & MacNeil, 2001). On B cells, NE participates in T-cell mediated IgG production (Alaniz et al., 1999; Kohm & Sanders, 2001), while the effects of NE over T lymphocytes is more complex and varies according to the cellular stage of maturation and timing of exposure. Depending on the stage of maturation of T $CD8^+$ cells, exposure to NE may either promote or decrease their cytolytic activity (Nance & Sanders, 2007). Similarly, exposing Th1 cells to NE before their activation decreases the synthesis of IL-2 and IFN-gamma, while exposing them to NE after activation increases the synthesis of IFN-gamma (Nance & Sanders, 2007). In any case, the overall effect of NE over adaptive immune responses is also considered to be anti-inflammatory, inhibiting Th1 cell differentiation and promoting Treg-suppressive activity (Elenkov, Wilder, Chrousos, & Vizi, 2000; Guereschi et al., 2013).

After SCI, immune cells may be subjected to persistent or more intense exposure to NE, which results in immunosuppression (Prass et al., 2003). A factor that may dramatically affect the sympathetic dysregulation-induced immunodepression is the lesion level, being lesions at T5 or above associated to a greater impairment of the immune system both in patients and in experimental animal models (Brommer et al., 2016; Lucin et al., 2007; Lucin et al., 2009). This observation coincides with the fact that most of the sympathetic innervation of immune organs arise from preganglionic neurons located below T5. The innervation of lymph nodes is not resolved, but it is considered to originate from spinal segments close to their location in the body (Nance & Sanders, 2007). Thymus receives most of its innervation from above T5, specifically between T1 and T7 (Trotter et al., 2007). In any case, the sympathetic dysregulation induced by SCI suppresses immune cells in the decentralized lymphoid organs. This statement is supported by direct experimental evidence showing that immune suppression effects depend on beta-2-adrenergic stimulation and may be reverted by receptor antagonists (Table 1). Indirect evidence is further provided by the observation of a relationship between lesion level and extent of immunodepression (Table 2).

TABLE 1 Effects of SCI over immune cells with experimental evidence of dependence on beta-2-adrenergic receptor stimulation.

Experimental evidence shows that SCI-induced immune suppression effects depend on beta-2-adrenergic stimulation and may be reverted by receptor antagonist. *SCI: spinal cord injury.*

TABLE 2 Effects of SCI over immune cells dependent on lesion level.

Cell type	Effect	References
B cells	Decreased number	Lucin et al. (2007), Held, Steward, Blanc, and Lane (2010), Zhang et al. (2013)
T cells	Decreased number	Lucin et al. (2009)
$CD4^+$ T cells	Decreased number	Zhang et al. (2013)
NK cells	Decreased number	Herman et al. (2018)
Dendritic cells	Decreased number	Iversen et al. (2000)

The observation of a relationship between the injury level and severity and the extent of immunodepression highlights the effects of SCI over immune cells. *SCI: spinal cord injury.*

There is evidence of the contribution of sympathetic overactivation to immune depression after SCI results from autonomic dysreflexia crises, potentially triggered by any sustained sensory stimuli entering the spinal cord below the lesion level. This occurs mainly in patients with severe lesions above T5 because these injuries render without inhibitory supraspinal inputs the SPNs that control abdominal circulation (Weaver et al., 2002). As a consequence, SPNs overactivation occurs and results in vasoconstriction and hypertension. As a counteractive measure it is triggered a vagal response that induces vasodilatation (only successful above the lesion level) and bradycardia, which may be life-threatening if derives into a cardiac arrest. It has been experimentally proved that in these crises, the overactive sympathetic response further aggravates immunodepression in animals with high thoracic (T3) SCI (Zhang et al., 2013), which may help to explain why infections result in morbidity and mortality among patients with tetraplegia compared to patients with paraplegia.

Another potential symptom of immunodepression driven by the autonomous nervous system is the "inflammatory reflex" (Pavlov & Tracey, 2017). When the vague nerve is stimulated, spleen macrophages are polarized into an anti-inflammatory profile. Evidence shows that the spleen does not receive parasympathetic innervation. However, the vagus nerve synapses with sympathetic post-ganglionic neurons in the celiac ganglion, eliciting the release of NE in the spleen. In response, T lymphocytes produce acetylcholine, which acting on alpha-7-nicotinic receptors expressed by macrophages inhibits the production of TNF-alpha, IL-1 beta and IL-18 by these cells. The contribution of the inflammatory reflex to SCI-induced immunodepression is not elucidated, but it seems reasonable to believe that it could be triggered by the vague nerve reflex that takes place during autonomic dysreflexia crises.

Dysregulation of the hypothalamic-pituitary-adrenal axis

The activation of the HPA axis after SCI is well documented by the increase of blood serum glucocorticoids (GCs) in patients and in experimental animals. Besides the direct immunosuppressive actions of GCs on immune cells, glucocorticoids (GCs) and NE synergize to modulate immune cell function. GCs increase the affinity and persistence in the cell membrane of beta-2-adrenergic receptors (Davies & Lefkowitz, 1981; Mak et al., 1995) while NE potentiates GCs signaling (Rangarajan, Umesono, & Evans, 1992). As such, when cortisol and the NE analog terbutaline are added together, they synergize to induce apoptosis of B and T cells in vitro (Lucin et al., 2009). Notably, the spleen atrophy and the decrease in the number of splenocytes induced by an experimental SCI in T3 is partially reverted by the join administration of antagonists of beta-2-adrenergic and GC-receptors (Lucin et al., 2009). In addition, it should also be considered that adrenal glands are innervated by the SNS, which induces the release of GCs.

Leading infection diseases in spinal cord-injured patients

Infection is one of the leading complications of inpatients, especially severe for SCIP due to the risk of death when it occurs a progression to a bloodstream infection. These patients have a greater predisposition to suffer infectious diseases because of their required use of medical devices such as intravenous and urinary catheters or ventilators. Special conditions suffered by these patients such as lack of mobility or bladder and respiratory dysfunctions contribute to a higher level of infection (Esclarín de Ruz et al., 2009).

There are two main features that make diagnosis of infection particularly challenging in SCIP. First, their loss of feeling can mask standard symptoms which make its diagnosis more difficult to diagnosis. Second, there are also some other

described conditions that can simulate an infection, but they are really the manifestation of another disease with no infection as it occurs in hyperthermia, abdominal retention, and pulmonary embolism or collapsed lung (Esclarín de Ruz et al., 2009).

In general terms for treatment, it is strongly recommended to use narrow-spectrum and less toxic antibiotics to avoid eliminating patient's native bacterial flora. It is also important to choose an appropriate directed antibiotic therapy to avoid the appearance of resistant bacteria.

The major infections that suffer SCIP are explained below (Table 3).

Urinary tract infections (UTI)

UTI are the most frequent cause of infections (95%) in SCIP. They increase the risk of morbidity and mortality because of interruptions of rehabilitation treatment, required visits to the emergency room, and progression to a sepsis. The latter can make SCIP more likely to develop an immunodeficiency syndrome that facilitates the appearance of recurrent UTI (Craven et al., 2019; Esclarín de Ruz et al., 2009). *Escherichia coli*, *Klebsiella pneumoniae*, and *Proteus mirabilis* are the most frequently involved pathogens causing an UTI (Skelton-Dudley et al., 2019).

Physiopathology and etiology

Neurogenic bladder presents overdistension and high pressure due to the interruption of its voiding process. This produces an ischemia of the bladder's wall, which causes bacteria to invade its submucosal layer, and starts the UTI. If this process repeatedly occurs, collagen forms a scared tissue that replaces muscle fibers from the bladder's wall, which decreases bladder's wall compliance. This leads to increase ischemia of the bladder's wall and bladder's overdistension (Fig. 1) (Linsenmeyer, 2018).

To avoid high intravesical pressure and overdistension of the bladder's wall, more than a 60% of SCIP need a medical device to facilitate their bladder voiding such as an intermittent self-catheterization (ISC), an indwelling urethral catheter (IUC) or a suprapubic catheter (SPC). ISC is the gold standard method because it allows a cyclic emptying and filling of the bladder, comparable to the physiological bladder's functioning. Some studies as Kinnear et al., 2020, suggest that ISC is associated with lower rates of UTI when comparing with other medical devices. Despite that, SCIP who use ISC are likely to suffer UTI when they drink plenty of fluids or they do not practice the voiding method regularly, because of an overdistension of the bladder's wall. It becomes worse when patients have an overactive bladder and/or a decreased bladder function (Kinnear et al., 2020).

TABLE 3 Principle infection features in SCIP.

	UTI	PI	Covid-19
Frequency	It is the most frequent cause of infection (95%) in SCIP	• The 50% of SCIP who suffer acute tetraplegia develop pneumonia during acute hospitalization • PI and respiratory failure are the major causes of death in this population	Unknown but lower than expected
Pathogens	• *Escherichia coli* • *Klebsiella pneumoniae* • *Proteus mirabilis*	• Pneumococcus, Pseudomonas (outpatients) • No data (inpatients)	SARS-CoV-2
Etiology	• Changes due to neurogenic bladder produce an overdistension of the bladder, high intravesical pressure and bladder compliance decrease that can lead to an UTI • Medical devices that are used for facilitating bladder voiding can lead to an UTI as well	• The dysfunction of inspiratory and expiratory muscles, the increased risk of dysphagia disorders and the changes inside lung that produces a neurogenic pulmonary edema can lead to a PI • Medical devices to assist with breathing can lead to a PI as well	• Immunosuppression induced by SCI • Neuromuscular respiratory failure due to respiratory muscles weakness and clearance secretions' decrease in SCI levels of injury above T6–T8

Continued

TABLE 3 Principle infection features in SCIP—cont'd

	UTI	PI	Covid-19
Diagnosis	• It is necessary to differentiate between: - Asymptomatic bacteriuria/ bladder colonization: - $\geq 10^2$ cfu/mL bacteriuria at sediment - or any bacteria detected at sediment when using IUC - no symptoms - [a]UTI: - bacteriuria (with one primary organism detected at culture) - one bladder symptom at least: - hematuria - new/increased incontinence - change in urine odor/clarity - pyuria - one general symptom at least: - fever - acute autonomic dysreflexia - acutely increased spasticity - sepsis - persistent fatigue - vomiting • When symptoms appear, urine and blood cultures are required • When symptoms persist, it may be necessary to carry out additional test as ultrasounds, cystoscopy or kidney scan, to rule out complications (hydronephrosis, vesicoureteral reflux, urinary lithiasis or kidney abscesses) • Blood biomarkers (procalcitonin and interleukin-6) has shown poor evidence in ITU detection	• Clinical symptoms: fever, dyspnea, secretions • Chest X-ray that shows infiltrates within lungs • Alterations in blood gas analysis • Leukocytosis • Culture and sputum Gram stain: – when NOT wearing an artificial airway: Sputum culture (>25 polymorphonuclear leukocytes and < 10 epithelial cells per field) – when wearing an artificial airway: - bronchoalveolar lavage sample: $>10^4$ cfu/mL - tracheal aspiration sample: $>10^6$ cfu/mL	• Mild symptoms of onset: hypoxia, secretion clearance impairment could be the only symptoms of onset; but SCIP can also present fever, dyspnea, fatigue, anosmia, ageusia, arthromyalgias, and headache • Close observation to neurofunctional outcomes, especially with the help of the International Standards for Neurological Classification of the Spinal Cord Injury (ISNCSCI) Worksheet, is needed to know if this infection produces sensory and motor deficits in these patients • Whenever those symptoms are suspected, it is needed to make a RT-PCR SARS-CoV-2 from nasopharyngeal or bronchial aspiration test to confirm the infected condition • Other paraclinical tests: Chest X-ray (to explore infiltrates at lungs), gas blood analysis (to explore ventilation perfusion state), and a blood analysis (to rule out lymphopenia, increase of D-dimer, ferritin and IL-6 • After 7–14 days from the onset of the symptoms, if patient presents a favorable clinical evolution, a serological SARS-CoV-2 should be done to look for IgM and IgG levels
Treatment	• The choice of the most appropriate antibiotic treatment depends on culture results • Long-term antibiotic treatment (from 7 to 14 days) is recommended	• Prompt empirical antibiotic treatment is needed - [b]Community acquired pneumonia - empiric anti-pseudomonal coverage is recommended - optimize secretion mobilization: • Multi-modal treatment • Quad coughing • Mechanical insufflator-exsufflator - [b]Early hospital-acquired pneumonia - empiric antibiotic treatment depends on most common pathogens for each hospital, ICU and anti-microbial susceptibility patterns of each community • It is recommended to use agents from a different antibiotic class than the patient has recently received	• The same as general population • In these patients, respiratory rehabilitation is especially important due to their condition of respiratory muscle weakness (secretions' clearance therapies, lower and upper active-assisted or passive kinesiotherapy, and relaxation exercises, and a positive expiratory pressure exercises with a Threshold PEP device to optimize the alveolar recruitment) • It is mandatory that Physiotherapists use PPE for self-protection

TABLE 3 Principle infection features in SCIP—cont'd

	UTI	PI	Covid-19
Prevention	• Minimize urinary retention: anti-cholinergic medications or onabotulinum toxin A (Botox) injections for overactive bladders • Change bacterial flora of the bladder: - urine acidification (methenamine hippurate) - bacterial interference • Strengthen the host: - probiotics - proanthocyanidins (cranberry extracts) - immune biotherapy • Reduce biofilm formation: - D-mannose - nanoparticles - to cover the catheter with hydrophilic material - bacteriophages	• [b]Outpatients: - annual Influenza and Pneumococcal polysaccharide vaccines - aggressive mobilization of secretions • [b]Inpatients: - standard precautions - hand washing - gloving and gowning - to perform tracheal and nasopharyngeal respiratory techniques and cares under aseptic conditions - to consider non-invasive positive-pressure ventilation instead of invasive ventilation - to perform orotracheal rather than nasotracheal intubation whenever possible - to clear secretions - to avoid saliva or respiratory secretions microaspiration by raising the head of the bed from 30 to 45 degrees - to perform pre-operative breathing exercises and post-operative incentive spirometry - to remove patients out of bed as soon as possible - to prevent hospital-acquired, ventilator associated, and healthcare-associated pneumonia	• Isolation and hygienic measures, the same as in general population. • Caregivers and health workers need to use PPE for self-protection.

Pathogens, frequency, etiology, diagnosis, treatment, and prevention strategies of the main infections that affect SCIP. *Covid-19*: coronavirus disease 2019; *ICU*: intensive care unit; *PEP*: positive expiratory pressure.; *PI*: pulmonary infections; *PPE*: personal protective equipment; *SARS-CoV-2*: severe acute respiratory syndrome coronavirus 2; *SCIP*: spinal cord-injured patients; *UTI*: urinary tract infections.

Diagnosis

First, it is important to provide an early UTI detection. For this purpose, it is necessary to differentiate between asymptomatic bacteriuria and symptomatic UTI. The first one appears when there is a count of 10^2 cfu/mL or higher at the urine sediment, and when any bacteria are detected with the use of IUC. In this situation, the patient shows no symptoms, and it is considered a colonization of the bladder. This situation is different from an UTI because colonization does not need to be treated as it may play a protective role to the bladder flora (Kirshblum et al., 2011; Linsenmeyer, 2018). To make the diagnosis of UTI, the Experts in Urohealth and/or UTI recognition and management and the SCI-High Project Team at Craven et al. (2019), propose the following criteria: bacteriuria should be confirmed with at least one germ in the urine culture, at least one bladder symptom (hematuria, change in urine odor and clarity, new or increased incontinence, pyuria) and at least one general symptom (fever, sepsis, acute autonomic dysreflexia, persistent fatigue, acutely increased spasticity, vomiting, etc.).

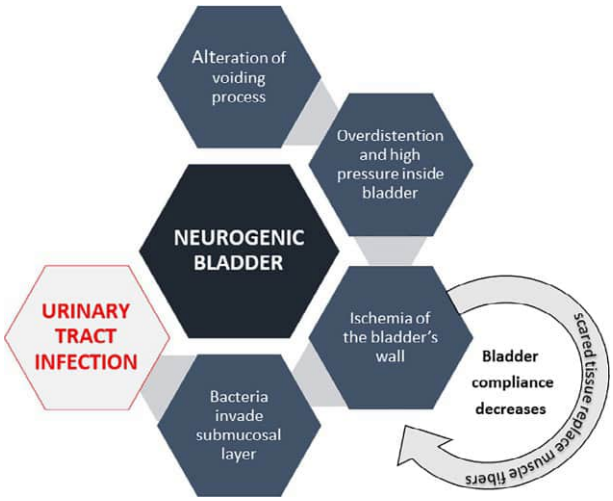

FIG. 1 Physiopathology of urinary tract infections. Step-by-step summary of the sequence of events leading to urinary tract infections (UTI) in SCI neurogenic bladder.

When those symptoms appear, it is necessary to take a urine and a blood culture in order to prescribe an appropriate antibiotic treatment to reduce antibiotic resistance and other associated complications in these patients.

It may be useful to practice a urine sediment because the majority of patients wearing a IUC present leukocyturia (50 leukocytes or more per field). The absence of leukocyturia excludes the diagnosis of UTI. This test has a high negative predictive value. Pyuria is only significant when there is also leukocyturia (Esclarín de Ruz et al., 2009).

If, in spite of an appropriate antibiotic treatment, symptoms persist, it may be necessary to carry out some additional tests such as ultrasound examination, cystoscopy, or kidney scan, to look for a structural cause or a complication being the leading cause of the persistent UTI (hydronephrosis, vesicoureteral reflux, urinary lithiasis, or kidney abscesses).

Blood biomarkers have shown poor evidence in the detection of UTI. Procalcitonin has been described as a biomarker in the diagnosis of UTI and pyelonephritis in pediatric population, but not in adults. IL-6 could help to differentiate between UTI and pyelonephritis, but further validation is needed yet (Skelton-Dudley et al., 2019).

Treatment and prevention

SCIP develop complicated UTI because of the urinary tract dysfunction. Because of this reason, it is necessary to follow a long-term antibiotic treatment from 7 to 14 days. To avoid the increased likelihood of anti-microbial resistance and to reduce the administration of wide spectrum antibiotics, it is necessary to perform a urine culture to select the most appropriate antibiotic treatment (Esclarín de Ruz et al., 2020).

Though some studies advise using prophylactic antibiotics as nitrofurantoin to prevent catheter associated UTI (Chew et al., 2019); the truth is that more consistent evidence is required to make this recommendation in a safe way to compensate the risk of resistances appearance derived from the use of these antibiotics (Skelton-Dudley et al., 2019), because there are some other studies like Morton et al. (2002), which show that using prophylactic antibiotics is worthless as it does not decrease the number of UTI, and even may be harmful, as it reduces asymptomatic bacteriuria while increasing antibiotic resistance.

To prevent recurrent UTI in SCIP it is desirable to improve patients' conditions minimizing urinary retention and optimizing urinary voiding, using anti-cholinergic medications or onabotulinum toxin A (Botox) when they have an overactive bladder. Also, it is important to correct anatomical problems like urethral stricture or bladder calculi (Linsenmeyer, 2018).

There are other prevention strategies for SCIP with recurrent UTI. The most commonly used are: (1) changing the bacterial flora of the bladder with urine acidification; or (2) strengthening the host by administering probiotics, proanthocyanidins such as cranberry extracts or D-mannose (to reduce biofilm formation on the bladder and catheter wall). In the foreseeable future, clinicians will also have nanoparticles capable of inhibiting biofilm formation by *E. coli* and *Staphylococcus aureus*, but this promising strategy is currently in the pre-clinical phase. To cover the catheter with hydrophilic material before its introduction to the bladder delays and decreases the number of UTI in acute SCI (Cardenas et al., 2011) by blocking the biofilm catheter formation. The use of bacteriophages that are responsible for producing a depolymerase

enzyme that breaks the extracellular polysaccharide matrix of the biofilms on urinary catheter, are also useful when the patient has developed antibiotic resistance because, when antibiotic-resistant bacteria become resistant to the phage, in some cases, the bacterial sensitivity to antibiotics is restored. Also, immune biotherapy uses the administration of antigenic components to be recognized as "danger signals" which contribute to activate the innate immune system as a prophylactic method (Linsenmeyer, 2018).

Pulmonary infections (PI)

The 50% of SCIP who suffer acute tetraplegia develop pneumonia during acute hospitalization and rehabilitation (Schilero et al., 2005). PI and respiratory failure are major causes of death in this population (Yong et al., 2012). Review study by Burns (2007) has identified Pneumococcus as the first leading pathogen causing pneumonia in outpatients with SCI, while Pseudomonas is the second one. Conversely, there are no published data on etiologic pathogens that cause pneumonia during acute hospitalization and rehabilitation for these patients. It is assumed that the etiology of a nosocomial pneumonia depends on the type of hospital, ICU, and anti-microbial susceptibility patterns of each community (Díaz, Martín-Loeches, & Vallés, 2013).

Review study by Burns (2007) also shows that in ventilator-dependent patients, more than 90% of patients suffering from pneumonias and requiring hospitalizations have previously developed upper respiratory tract infections.

Physiopathology and etiology

Depending on the level and severity of the SCI, there are different mechanisms that are thought to be involved in causing pneumonia. In complete lesions above C3, the respiratory muscles are paralyzed. In C3–C5 lesions, despite varying degrees of phrenic nerve injury, respiratory neuromuscular activation is preserved but dysfunctional. Lesions below C5 retain some degree of ventilatory function due to intercostal and abdominal muscles, but above all, both diaphragms are preserved. These three situations involve inspiratory and expiratory hypofunction, which leads to dyspnea, decreased vital capacity, ineffective cough and problems with mucociliary clearance (Yong et al., 2012), and also they are more likely to suffer dysphagia disorders, especially due to tracheostomy, rigid fixation and high complete lesions due to the delay of mechanical ventilation weaning (Abel, Ruf, & Spahn, 2004). Apart from that, patients with low thoracic SCI, who retain good muscular respiratory function, may develop neurogenic pulmonary edema due to pulmonary vein constriction, increased pulmonary capillary hydrostatic pressure, alveolar damage and increased capillary permeability due to transient sympathetic discharge, which is underdiagnosed and provides the right environment for developing PI (Yong et al., 2012) (Fig. 2).

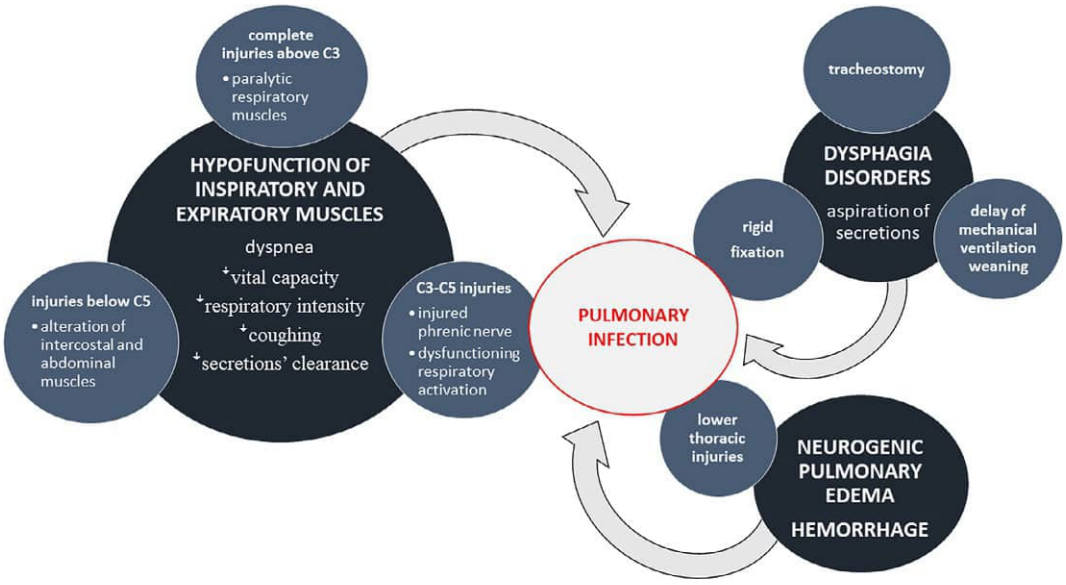

FIG. 2 Physiopathology of pulmonary infections. SCI-induced inspiratory and expiratory muscles hypofunction, dysphagia disorders, and neurogenic pulmonary edema can lead to develop a pulmonary infection in spinal cord-injured patients.

Diagnosis

Fever, respiratory symptoms as dyspnea or secretions, chest X-rays with infiltrates within lungs and alterations in blood gas analysis, and leukocytosis determine a diagnosis of pneumonia. To administrate an appropriate antibiotic treatment, it is necessary to make a culture and a sputum Gram stain.

In cases where a patient is not wearing an artificial airway, it is sufficient to make a sputum culture. A sample of >25 polymorphonuclear leukocytes and <10 epithelial cells per field is considered representative of the lower respiratory tract. In cases where patients are wearing an artificial airway, it is necessary to take a sample by bronchoalveolar lavage or a tracheal aspiration. An infection is diagnosed when there are $>10^4$ cfu/mL in bronchoalveolar lavage sample or $>10^6$ cfu/mL in tracheal aspiration sample (Esclarín de Ruz et al., 2020).

Treatment and prevention

While obtaining a culture, and before administrating a specific antibiotic treatment it is necessary to use a prompt empirical antibiotic treatment for avoiding respiratory infection progression. The choice of empiric antibiotic coverage depends on the most common pathogens for each hospital, ICU and anti-microbial susceptibility patterns of each community.

Burns (2007) recommends the management of community acquired pneumonia to consider empiric anti-pseudomonal coverage. It is also recommended to optimize secretion mobilization by multi-modal treatment, quad coughing or mechanical insufflator-exsufflator. To choose the empiric antibiotic coverage for SCIP with an early hospital-acquired pneumonia, it is recommended to use the same medications used for hospital-acquired pneumonia in patients without SCI, as the etiologic organisms for pneumonia that develop during acute care in SCIP are still undescribed. It is recommended to include agents from a different antibiotic class than the patient has received recently.

To prevent respiratory infections in outpatients with spinal cord injury, Burns (2007) recommends annual Influenza and Pneumococcal polysaccharide vaccines, and aggressive mobilization of secretions. In the case of SCI inpatients, the same author also recommends using the standard precautions (hand washing, use of gloves and gowns), performing the various tracheal and nasopharyngeal respiratory techniques and cares under aseptic conditions, as well as considering non-invasive positive pressure ventilation instead of invasive ventilation, opting for orotracheal instead of nasotracheal intubation whenever possible, clear secretions, avoid saliva or respiratory secretions microaspiration by raising the head of the bed from 30 to 45 degrees, perform pre-operative breathing exercises and post-operative incentive spirometry, and remove patients out of bed as soon as possible, to prevent hospital-acquired, ventilator-associated and healthcare-associated pneumonia.

There are other less frequent but also important infections that can affect SCIP such as pressure ulcer infections, surgery wound infections, intra-abdominal abscesses causing acute abdomen, sepsis… that are not explained here but expert SCI physicians need to know deeply to provide the acutest diagnosis and the best care and treatment to these patients. The latter review of the most frequent infections of SCIP (UTI) and the more severe ones (PI), pretend to help to achieve the greater understanding of the new Covid-19 infection in these patients.

COVID-19 disease: A new infectious normality in spinal cord-injured patients?

As it is well established, SCIP can be quite fragile. When Covid-19 pandemic started, we feared that they would have to face poor evolution and harsh prognosis, because of the presence of immunosuppression and induced autoimmunity, but above all, because of the respiratory muscles' weakness in all those cases with injury levels above T6–T8 (López-Dolado & Gil-Agudo, 2020). In addition, the mortality rate from influenza pneumonia was known to be higher than that of the general population (Soden et al., 2000). However, this grim prognosis does not seem to be confirmed. In fact, it has been reported that SCIP with concomitant Covid-19 infection show mild initial symptoms and better outcomes, even being aged over 60 and/or presenting clinically severe phenotypes (D'Andrea et al., 2020; Rodríguez-Cola et al., 2020), (Table 3). This apparently "indifferent" behavior toward Covid-19 infection has also been described in some autoimmune osteoarthropathies such as rheumatoid arthritis, also in those patients treated with biological disease-modifying anti-rheumatic drugs (bDMARDs) or Janus kinase inhibitors (JAKi) (Stradner et al., 2020). Data regarding Covid-19 and SCI are sparse, and further studies are needed to investigate the course of Covid-19 in SCIP, whether or not they have comorbidities and whether they are acute or chronic, but two simple although important points must be taken into account. First of all, the typical immune response involved in viral infections is sensibly different than in bacterial ones. Viruses are intracellular pathogens while bacteria are extracellular, so the role of CD8s and NK is quite different in both cases (see above). Second, as important as the pathogen in clearing up any infection is the immune system that fights against it, so in this regard, the SCIP cannot be considered as a homogeneous population. Factors such as advanced age, the presence of

comorbidities or long-term SCI chronic stages would negatively influence the immune response and could conditionate different risk levels (Monroe et al., 2019). Finally, with the available data to date, it is not possible to support or reject that Covid-19 infection is less symptomatic or severe in SCIP, since the use of drugs that dampen the local pulmonary inflammatory response is common in this population and the available data mostly come from case reports or at most from case series, valuable work for sure, but with restricted levels of evidence.

Another interesting aspect is the thrombogenic nature of Covid-19 shared by SCI. Using proteomic analysis to look for diagnostic biomarkers of Covid-19 infection in a cohort of SCIP, a specific role of heparin response to Covid-19 infection was found, supported by a significant correlation with proteins implied in coagulation/platelet activation. In this study, SCIP with Covid-19 receive from the moment of diagnosis prophylactic heparin, a common practice with these persons when bedridden is needed to avoid typical thrombotic and embolic complications (Calvo et al., 2020). Interestingly, heparin has demonstrated therapeutic potential against SARS-CoV-2 infection as a competitive inhibitor in general population Covid-19 patients.

It is well established that close to half of the hospitalized Covid-19 patients exhibit neurologic manifestations at the onset of the infection. To the author's knowledge, no study has been found that specifically analyzes this aspect in SCIP, although myalgias, headache, anosmia, and ageusia have frequently been found (Liotta et al., 2020). Sensory and motor deficits, barely been reported in the general population, have not been detected at all in SCIP, which does not mean that they have not appeared, but that we have not been able to detect them. Close observation to the neurofunctional outcome of the Covid-19 SCIP in the near and further future will permit to address this aspect.

The prevalence of Covid-19 infection among acute or chronic SCIP is unknown, but judging by the number of published cases, it seems lower than that of the general population (D'Andrea et al., 2020; López-Dolado & Gil-Agudo, 2020; Rodríguez-Cola e al., 2020). Part of the explanation could lie in the lower number of social contacts experienced by individuals who have reduced mobility and disability, in addition to the hygienic measures usually and constantly taken by their caregivers, which are similar to the measures that protect general population from Covid-19. The risk of transmission for the caregivers is nevertheless, another matter. Because being paucisymptomatic, Covid-19 infection could go unnoticed, turning the SCIP into a reservoir that would substantially increase the risk of contagion their caregivers. Therefore, caregivers and health providers must have access to adequate personal protective equipment (PPE) (Cossarizza et al., 2020). On top of that, both patients and their caregivers have experienced this pandemic, anxiety, loneliness and sadness, emotions that, if not addressed, will have negative impact on the health of all those groups (Taylor et al., 2020). The current pandemic has severely restricted SCIPs' access to health services, either for clinical control and follow-up, or to receive rehabilitative interventions. It is our vocation and obligation to use all the tools at our disposal, like the telemedicine platforms to maintain a safe, economical method of patient care.

Despite the burden of this worldwide disease there is no specific drug available to combat Covid-19. Vaccine efficacy depends largely upon the vaccine target and platform. Generally, the clinical development of a new vaccine requires many years of efforts in this area. However, having the results of previous efforts related to SARS-CoV and MERS vaccine research available, this time it has been possible to develop several vaccines, yet almost ready for their massive use in general population. There are no data to support the preferential vaccination of SCIP if the expressiveness and severity of the Covid-19 infection is taken into account. However, the fact that they can become virus reservoirs, and therefore, a source of transmission, is a compelling reason to recommend its extensive vaccination. Former experiences during previous pandemics, such as H1V1 or influenza, highlighted the need to make every effort not just to get the vaccine but to inform the target population to achieve sufficient vaccination rates. All possible efforts to ensure that accurate and clear information reaches the target SCIP must be done, since it is known that the better the information available on the disease and the vaccine, the higher the vaccination rate (LaVela et al., 2012). The medical community serving SCIP constitutes an exceptional group for quality information on Covid-19 vaccination to permeate (Locatelli et al., 2013). Thus, the current pandemic has shown us that from now on we should include in our health education programs all necessary information to protect SCIP against emerging pathogens and, among them, a better knowledge of available vaccines.

Applications to other areas of neuroscience

In this chapter we have reviewed the implication of the alteration of immune system in spinal cord-injured patients, and how this process leads the different infections that can suffer these patients. We also interlink the role of this immunosuppressed induced condition, with the current SARS-Cov-2 pandemic.

A better understanding about the interaction between the nervous system and the immune system could be reached by comprehending how SARS-Cov-2 virus affects patients with central nervous system diseases, such as in the spinal cord-injured patients, as Covid-19 influences the nervous system functioning and the immunity status as well. Due to its

neurotrophic feature, the deep knowledge of its structure, function, infection mechanism and characteristics, may help to improve the design of the current viral vectors applied at Neuroscience.

It should be an increasingly common requirement at the educational and clinical practice to include the study of the effects on our immune system in order to achieve the acutest and better understanding of every oldest known and new diseases. These diseases develop in a shared territory between neuroscience and immunology, so the deep knowledge of this space "in between" is a challenge, not only for physicians and immunologists, but also for neuroscientists, the spearhead of a successful knowledge in the research of central nervous system diseases and disabilities.

Mini-dictionary of terms

Respiratory syndrome coronavirus 2: Infection disease caused by Coronavirus that originates a severe damage to the lungs that involves a respiratory insufficiency, even in some cases, a breathing failure, requiring artificial ventilation supply.

Immunodepression: State of weakness of the immune system that delays and makes difficult to develop a prompt and active defense response against pathogens that invade human body. It has been demonstrated that spinal cord injury is a systemic disease which precipitates systemic changes that affect the immune system in this way.

Sympathetic nervous system: Part of the autonomic nervous system made up of neurons located from the first thoracic to the first lumbar segments which are presumed to carry out within its multiple functions, to innervate the primary and secondary lymphoid organs and modulate all the immune processes. Any process affecting this sympathetic nervous system, as spinal cord injury, could result in an alteration of the immune response of a patient.

Hypothalamic-pituitary-adrenal axis: Complex hormonal communicating system between the brain and different body glands that participate in different body responses, as the stress responses, energy metabolism, or the modulation of immune responses, as sympathetic nervous system does as well. In addition, adrenal glands, which are part of this axis, are innervated by the sympathetic nervous system. If a patient suffers a spinal cord injury, it will result in an alteration of all those responses by damaging the sympathetic nervous system and by altering this axis as well.

Bloodstream infection: Presence of pathogen organisms in the blood, having come directly from outside or being the spreading of a previously local infection. This is a severe infectious disease that can threat patient's life.

Native bacterial flora: Specific species of bacterial organisms that normally dwell different parts of human body without causing a disease. In fact, the loss of these bacterial organisms could imply the invasion from other pathogens that can lead an infection, so this native bacterial flora usually plays a protective role.

Neurogenic bladder: Dysfunction of the bladder due to a neurological damage that implies an overdistension of the bladder's wall and an increased high pressure inside due to the alteration of its voiding process. Therefore, patient suffers incontinence and urine retention that may need medications and/or medical devices to facilitate and normalize their bladder's voiding.

Recurrent urinary tract infection: Repeated infection of the urinary tract that does not disappear despite adequate anti biotic treatment. In spinal cord-injured patients, it should make consider the presence of a urinary complication as hydronephrosis, vesicoureteral reflux, urinary lithiasis, or kidney abscesses. First, it will be necessary to rule out these disorders to treat the infection successfully, later on.

Biofilm: Adherence of pathogens to the wall of artificial products that are in direct contact to body tissues, such as medical devices, that are able to produce a protective layer that make them resistant to standard antibiotic treatments. When it appears in a catheter and it remains unnoticed, the catheter biofilm becomes a leading cause of recurrent urinary tract infection and appearance of resistant bacterial pathogens.

Dysphagia disorders: Alteration of the deglutition process that implies the risk of passing food through airway by the larynx. It is a leading cause of pneumonia, which is considered to be the severest infection in spinal cord-injured patients because it can threat their life.

Neurogenic pulmonary edema: Fluid invasion of the alveolar spaces from the lungs due to an inflammatory cascade which is thought to be the result of the immune system's damage suffered in severe neurological injured patients. The resulting pulmonary edema could behave as an adequate environment for developing a pulmonary infection in these patients.

Telemedicine and telerehabilitation: Way of supplying a medical attention, or medical, and/or rehabilitation treatment that replace the classic patient's physical attendance at the place of the doctor visit, by a telephone or video consultation, which avoids patients' movements from home or familiar environment. It provides an effective source of access to medical healthcare to chronically affected patients as spinal cord-injured patients, who may find impairments to achieve transportations, especially during pandemic restriction period.

Key facts of "infections and spinal cord injury: Covid-19 and beyond"

Key facts of "immunosuppression due to spinal cord injury"

- Spinal cord injury is a systemic disease.
- Spinal cord injury induces an alteration of the immune system.
- This alteration of the immune system leads patients to suffer from infections.
- The better understanding of the modifications produced by the alteration of the immune system enables physicians and scientists to be able to appreciate the clinical presentations of these diseases, and patient's responses to treatments, as well.

Key facts of "Leading infection diseases in spinal cord-injured patients"

- Infection is one of the leading complications of spinal cord-injured patients because this disease can threat their life.
- Urinary tract infections are the most frequent cause of infection in these patients because they present a neurogenic bladder and they usually need to use medical devices to facilitate their bladder's voiding.
- Its acute diagnosis will be of great importance to establish a long-term and appropriate antibiotic treatment to avoid antimicrobial resistances and further complications.
- Pulmonary infections are the most severe cause of infection in these patients because they can lead to a respiratory insufficiency and breathing failure that can strongly threat patients' life.
- While waiting for etiologic organisms' results and before starting an adequate antibiotic treatment guided by those results, with the only clinical suspicion, physicians need to start an empirical antibiotic treatment, to avoid the progression of the infection.

Key facts of "Covid-19 disease"

- Most of the published studies show a tendency of milder initial symptoms and a less severe evolution of the Covid-19 disease in spinal cord-injured patients, but currently further validation is needed to support or reject that Covid-19 infection is less symptomatic or severe in this population.
- Covid-19 disease has shown a thrombogenic nature in spinal cord-injured patients that must be treated with heparins.
- In spite of coronavirus' neurotropism, it has not been detected a sensory or motor deterioration in spinal cord-injured patients due to Covid-19 disease yet; but close observation to the neurofunctional outcomes should be done to ensure this affirmation.
- As Covid-19 disease could go unnoticed, turning the spinal cord-injured patients into a reservoir that could increase the contagion of their caregivers, medical community serving these patients should do every possible effort to provide appropriate healthcare educational programs with all the information needed to protect them from emerging pathogens that include the better knowledge of the available vaccines.
- Telemedicine has demonstrated to be a useful and effective tool to provide access to medical healthcare to chronically affected patients as spinal cord-injured patients, especially during this pandemic restriction period.

Summary points

- Spinal cord injury induces not only a loss of mobility and sensibility, but also numerous chronic disorders.
- Spinal cord-injured patients suffer a dysregulation of the sympathetic nervous system and the hypothalamic-pituitary-adrenal axis, which causes an alteration of all their immune processes.
- The combination of this situation with other locally impaired conditions provides a suitable environment for developing an infection.
- Urinary tract infections are the most frequent infections in these patients, because of the presence of a neurogenic bladder and the use of catheters to facilitate its voiding.
- Pulmonary infections are the severest ones, because of the respiratory muscle weakness, dysphagia disorders, pulmonary edema, and the use of ventilators to assist with breathing.
- The deep understanding of the physiopathology of these infections should help us to understand its appropriate diagnosis, treatment, and methods of prevention.

- The pandemic Covid-19, which is deadly hitting our general population, seems to show a tendency of milder initial symptoms and a less severe evolution in spinal cord-injured patients, but currently further validation is needed to support or reject it.
- The altered immune response could play a critical role in the clinical presentation of these patients.
- Telemedicine has demonstrated to be a useful and effective tool to provide access to medical healthcare to these chronically affected patients, especially during this pandemic restriction period.

Introduction

Spinal cord injury (SCI) is a significant global cause of mortality and morbidity. In 2007, the global incidence was estimated to be 23 cases per million per annum, ranging from 15 cases per million in Australia to 29 cases per million in sub-Saharan Africa (Lee, Cripps, Fitzharris, & Wing, 2014).

Most people with SCI sustain their injuries in their second or third decade of life. Because of improvements in both the acute management and long-term supportive care, their life expectancy after injury has increased significantly. As such, secondary diseases and impairments that are a direct consequence of the SCI have significant impacts for many years. Sleep disorders, especially sleep-disordered breathing (SDB), periodic and/or restless leg syndromes (PLM/RLS), and circadian rhythm disorders, are all prevalent disorders after SCI. This chapter focuses on these particular sleep disorders because while insomnia, generalized fatigue, and other sleep-associated disorders affect people living with SCI just as the general population, the increased prevalence and altered pathogenicity due to the spinal lesion per se of SDB, PLMs, and circadian rhythm disorders after SCI deserves special consideration (Sankari, Badr, Martin, Ayas, & Berlowitz, 2019). Population prevalence, known physiological differences in causation, response to therapies, and longer-term consequences of sleep disorders in these sleep disorders after SCI are discussed.

Diagnosis and Treatment of Spinal Cord Injury. https://doi.org/10.1016/B978-0-12-822498-4.00012-9

Sleep-disordered breathing

Sleep-disordered breathing is an umbrella term that includes obstructive sleep apnea (OSA), central sleep apnea (CSA), and sleep-related hypoventilation. OSA is repeated partial (narrowing/hypopnea) or complete (occlusion/apnea) closure and interruption to ventilation at the level of the upper airway during sleep. The drive to breath is generally maintained during OSA, whereas CSA is characterized by periods of diminished or absent ventilatory drive with associated reductions in ventilation. Both OSA and CSA result in periodic oxygen desaturation and fragmentation of sleep typically resulting excessive daytime sleepiness. Hypoventilation refers to periods during which arterial carbon dioxide homeostasis is not maintained because minute ventilation inadequately matches metabolism. The consequence of hypoventilation is a raised arterial carbon dioxide. All three disorders may exist separately or together in the same person and to various degrees over, and indeed within, sleep periods (Guilleminault, Tilkian, & Dement, 1976). The most common risk factors for OSA in the general population are being male and having a raised body mass index (BMI).

There is very little published research into respiratory sleep disorders in paraplegia. While little data reduces our ability to be certain, it is believed that the pathophysiology, risk factors and prevalence of respiratory sleep disorders in those living with paraplegia is not substantially different to the general population. Conversely, tetraplegia has been studied extensively. Despite substantial overall respiratory muscle weakness, (Berlowitz & Tamplin, 2013) tetraplegia is not routinely associated with hypoventilation, but rather with OSA (Berlowitz et al., 2019). The upper airway muscles derive motor innervation from the cranial nerves, predominantly the hypoglossal, rather than from the spinal segmental nerves. Hence, an injury that disrupts, for example, C6 should not have any effect on the genioglossus. Yet while OSA is highly prevalent (Fig. 1), hypoventilation appears rare at a population level. In a recent large, multi-center randomized controlled trial of continuous positive airway pressure (CPAP) for SDB in acute tetraplegia (Berlowitz et al., 2013), only eight of the 212 otherwise eligible participants (3.8%) were excluded due to hypoventilation ($PaCO_2 > 45$ mmHg) (Berlowitz et al., 2019). Hypoventilation has been reported, particularly at sleep onset in physiological studies (Bascom, Sankari, Goshgarian, & Badr, 2015) and in association with a reduced ventilatory reserve for carbon dioxide

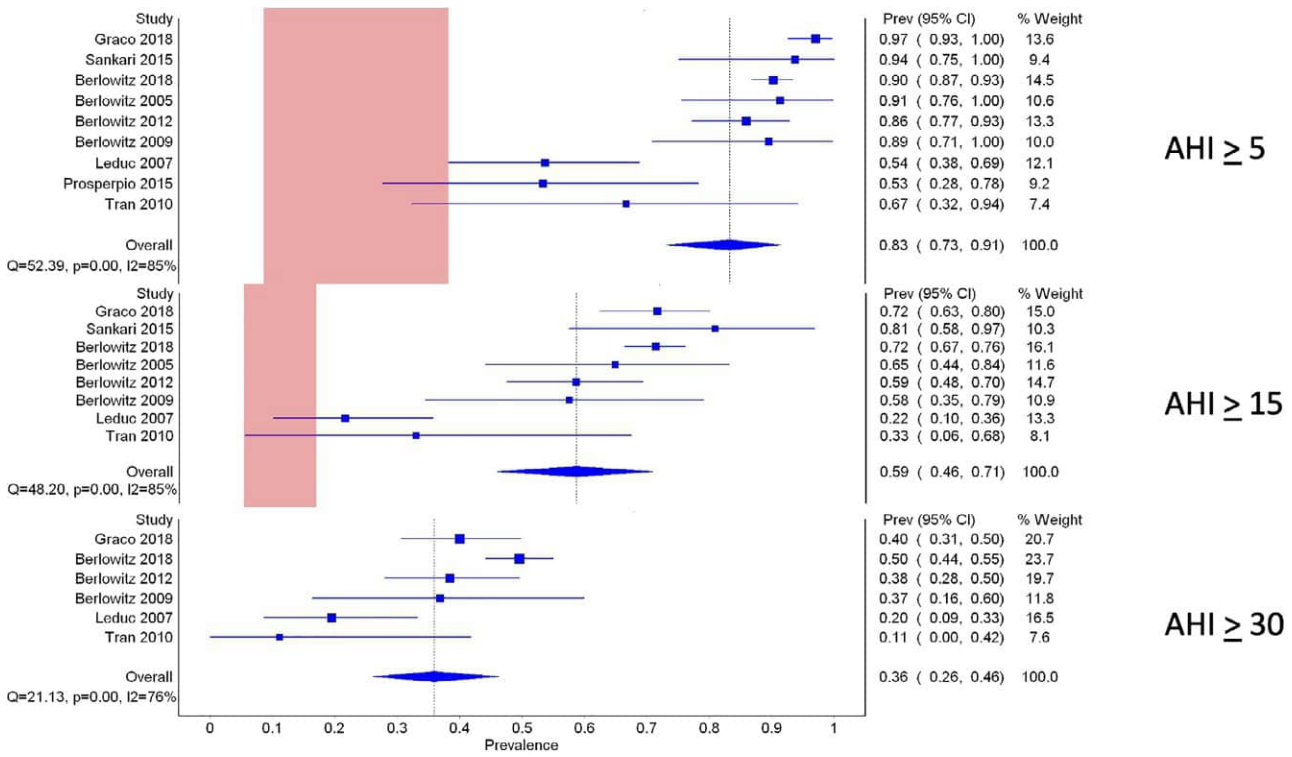

FIG. 1 Prevalence estimates and their relationships to general population data for mild, moderate, and severe sleep-disordered breathing in tetraplegia. Forest plots of individual study data, pooled estimates of prevalence in studies of people with tetraplegia, and ranges of general population estimates at mild (AHI > 5), moderate (AHI > 15), and severe (AHI > 30) levels of SDB severity (Graco, McDonald, Green, Jackson, & Berlowitz, 2021). These graphs illustrate the substantially higher prevalence of sleep-disordered breathing in tetraplegia across all ranges of severity. Solid bands across the mild and moderate data ranges are general population estimates ranges (Senaratna et al., 2017). *AHI* = apnea hypopnea index (measured in events per hour).

(Sankari, Bascom, Chowdhuri, & Badr, 2014), but there is little evidence for increased hypoventilation prevalence across all those living with tetraplegia. Clinically however, if a raised carbon dioxide is detected in a particular patient, this relatively rare sign demands immediate clinical attention.

Prevalence of sleep-disordered breathing after tetraplegia

The prevalence of disordered breathing during sleep is estimated to be between 9% and 38%, and increases with age (Senaratna et al., 2017). In previous cross-sectional population studies of sleep disorders in patients with tetraplegia, the prevalence of SDB has been estimated to be between 27% and 97% (Giannoccaro et al., 2013; Graco et al., 2018). However, a recent meta-analysis of the published population estimates in tetraplegia presented the pooled estimates at various cut-off severities (Graco et al., 2021). Twelve articles across 20 years were included, nine of which presented data amenable to meta-analysis (combined $n = 630$). The reported SDB prevalence rates from the 12 studies ranged from 46% to 97%. Following meta-analysis the mean prevalence of at least mild (apnea hypopnea index AHI $\geq$ 5 events per hour), moderate (AHI $\geq$ 15), and severe (AHI $\geq$ 30) SDB were 83% (95% CI = 73–91), 59% (46–71), and 36% (26–46), respectively. As illustrated in Fig. 1, the prevalence of SDB after cervical SCI is clearly elevated at all levels of severity compared with general population estimates (Senaratna et al., 2017).

Sleep-disordered breathing is an acute and direct consequence of cervical SCI

As noted above, the upper airway is innervated directly from the brain via the cranial nerves, not by the spinal segmental nerves. Notwithstanding this, an acute cervical spinal cord injury appears to directly compromise upper airway patency during sleep within weeks of the injurious event. Berlowitz et al. studied all patients presenting to the specialized SCI unit in Melbourne, Australia, over an 18-month period and undertook full, bedside polysomnography to determine when SDB appeared after injury (Berlowitz, Brown, Campbell, & Pierce, 2005). As illustrated in Fig. 2, approximately 10% of the cohorts were at increased risk of the SDB prior to injury as estimated by a prediction algorithm that incorporates signs and symptoms. Within 2 weeks of injury, the measured prevalence of clinically important disease had increased to 60% and peaked at over 80% 3 months after initial injury. Most people with SDB have an insidious onset of the disorder over a number of years as they age and gain weight. In contrast, tetraplegia appears to be the only model of acute SDB in humans. As such, the pathophysiology in acute tetraplegia is likely different from the general population and is not yet fully understood (Sankari et al., 2019).

Sleep-disordered breathing after tetraplegia has clinically important impacts

Alongside the cardinal SDB signs of nightly intermittent hypoxia, repeated arousals from sleep, and excessive daytime sleepiness, SDB is also associated with increased cardiovascular risk and clinically important degrees of neurocognitive dysfunction. In the general population, numerous reviews have described the deleterious impact of SDB on neuropsychological functioning and demonstrated impairment in the domains of attention, information processing, executive function, memory, and learning (Bucks, Olaithe, & Eastwood, 2013). While SDB in the general population is associated with

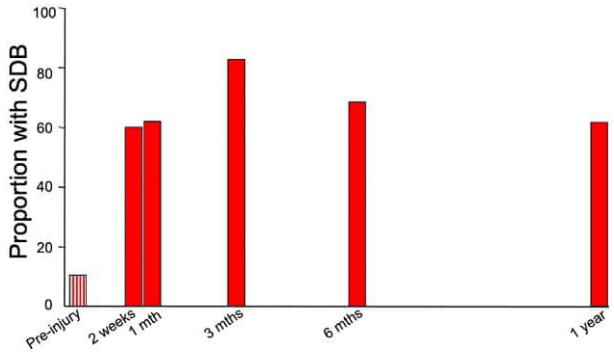

FIG. 2 Proportion of those with sleep-disordered breathing in a prospective, acute cohort study. Solid bar graphs refer to the proportion of the cohort with SDB at each assessment. The pre-injury proportion with an AHI score greater than 10 (vertical striped bar) was estimated using a prediction algorithm that incorporates, age, sex, body mass index and (participant recalled) symptoms to give a likelihood of an AHI > 10 (Berlowitz, Brown, Campbell and Pierce, 2005). *SDB* = sleep-disordered breathing as defined by a respiratory disturbance index (RDI) > 10 events per hour.

hypertension, altered diurnal blood pressure patterns and heart rate variability (HRV), these relationships are not as uniformly observed in those with tetraplegia and SDB. Goh and colleagues demonstrated that tetraplegia is associated with relative nocturnal hypertension and "reverse dipping" or a loss of the usual reduction in blood pressure overnight (Goh et al., 2018). In contrast, Sankari et al. have demonstrated that those with tetraplegia and SDB are also more likely to have diagnosed hypertension and cardiovascular disease (Sankari, Martin, & Badr, 2015). However, Fang et al. were unable to show any difference in the 24-h, night-time, and daytime blood pressure patterns in those with tetraplegia and mild, moderate, severe or no SDB (Fang, Goh, O'callaghan, & Berlowitz, 2018).

SDB has been associated with worse quality of life in tetraplegia. A study investigating the relationships between quality of life and sleep disorders in chronic tetraplegia measured both health-related quality of life (Assessment of Quality of Life) and SDB severity with a full, portable home-based sleep study (Berlowitz, Spong, Gordon, Howard, & Brown, 2012; Spong, Graco, Brown, Schembri, & Berlowitz, 2015). As illustrated in Fig. 3, quality of life and health utility scores were worse in the group with complete lesions compared with incomplete lesions. This single co-morbidity reduces health-utility by an approximately five times the minimally clinically important difference. As such, any effective treatment is likely to have an important impact on those living with both tetraplegia and SDB.

In patients living with chronic SCI, Sajkov et al. (1998) published neuropsychological evaluation data that were performed concurrently with a diagnostic sleep study in 40 people who had been living with tetraplegia for many years (McEvoy et al., 1995). The neuropsychological functions most affected were verbal attention and concentration, immediate and short-term memory, cognitive flexibility, internal scanning and working memory. These impairments are similar to those observed in the able bodied with OSA, which suggested that even if the pathogenesis of SDB is different immediately after SCI, the cognitive consequences of living with SDB for decades appear similar.

As noted earlier, our group recently completed a large, multi-center randomized controlled trial of CPAP for SDB in acute tetraplegia (Berlowitz et al., 2013; Berlowitz et al., 2019). Baseline data from that study was utilized to investigate the relationship between apnea severity and neuropsychological function in patients with acute-onset tetraplegia and SDB dysfunction (Schembri, Spong, Graco, Berlowitz, & Team, 2017). Study enrolment analyses showed more severe sleep apnea was significantly associated with poorer attention, information processing, and immediate recall. Higher pre-injury intelligence and being younger reduced the associations with sleep-disordered breathing; however, these protective factors were insufficient to counter the damage to attention, immediate recall, and information processing associated with the sleep-disordered breathing. As illustrated in Table 1, these deficits in attention and information processing, as measured by the PASAT, were clinically important, being well within the range of values reported in moderate to severe isolated head

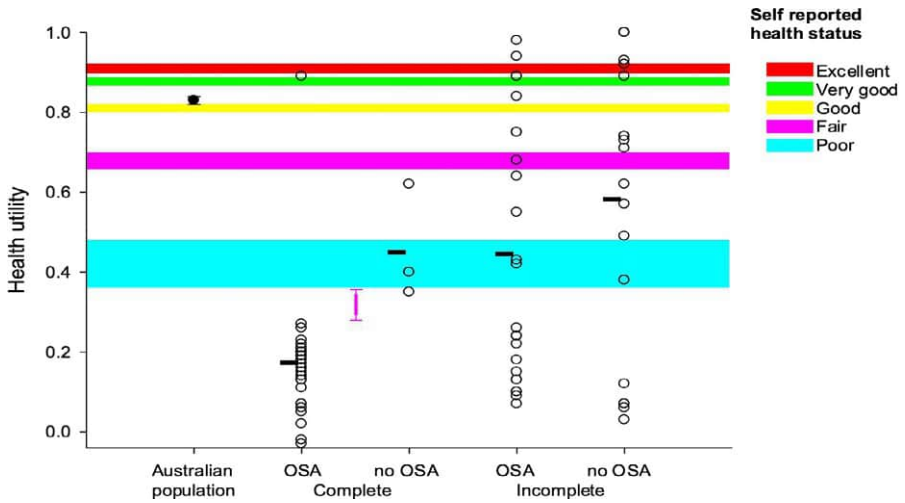

FIG. 3 Tetraplegia severity and obstructive sleep apnea independently modify health status. Colored bands represent the Australian population averages for categories of self-reported health status. Health utility ranges from one (self-rated "perfect health"), through zero (self-rated health state equivalent to death), and down to a health status of −0.04 (self-reported health status that is perceived to be "worse than death"). The Australian population average (95% confidence interval) score is located between "good" and "very good" (Hawthorne & Osbourne, 2005). The pink vertical bar represents the minimal clinically important difference in health status (0.06) and the associated confidence interval of this difference. People with tetraplegia are categorized by the presence or not of sleep apnea and of motor and sensory complete spinal injury (ASIA impairment scale A vs B, C, or D). Open circles represent individual participant scores, and the horizontal bars represent group mean values (Berlowitz et al., 2012). *OSA* = obstructive sleep apnea as defined by an apnea hypopnea index (AHI) > 10 events per hour.

TABLE 1 Attention and Information processing performance as measured by the PASAT performance in acute tetraplegia compared with other patient groups.

Group	PASAT score mean or range of reported means
Healthy controls	56–74
Chronic fatigue syndrome	62
Multiple Sclerosis	45–54
Mild traumatic brain injury	39–57
Moderate to severe traumatic brain injury	19–51
Mild-moderate SDB in acute tetraplegia	*48*
Severe SDB in acute tetraplegia	*33*
Overall baseline COSAQ	*41*
Overall end study COSAQ	*49*

Scores are represented as the percentage of correct responses, and thus higher percentages indicate better performance. Data in italics for SDB in acute tetraplegia are taken from the CPAP for OSA in Quadriplegia (COSAQ) trial (Berlowitz et al., 2013; Berlowitz et al., 2019; Schembri et al., 2017). Comparison values are from a review of the range of values for the PASAT across a number of research study samples (Tombaugh, 2006).

injury (Tombaugh, 2006). Attention and information processing as measured on the PASAT naturally decline as we age, but the reduction seen in those with severe SDB compared with milder SDB was equivalent to an additional 31 years of ageing.

Why do people with tetraplegia have sleep-disordered breathing, predominantly obstructive sleep apnea?

It is apparent that SDB in SCI is not simply due to peri-accident neuroanatomical compromise; however, the exact etiology remains unknown. Obesity, as measured by increased weight, body mass index (BMI), waist, abdominal, and neck girth, is associated with OSA in both SCI and the general population (Berlowitz et al., 2012; Graco et al., 2021). Obesity results in upper airway narrowing in both lateral pharyngeal tissues and the tongue in the general population, as well as those with SCI (Kim et al., 2014; O'donoghue et al., 2018). Truncal obesity reduces lung volume and distal tethering of the trachea which in turn leads to decreased upper airway caliber during sleep (Owens, Malhotra, Eckert, White, & Jordan, 2009). In chronic SCI, several authors have observed associations between OSA prevalence and increasing age, BMI and neck circumference, (Berlowitz et al., 2012; Burns, Kapur, Yin, & Buhrer, 2001; McEvoy et al., 1995; Stockhammer et al., 2002) but these relationships appear weaker in the immediate period after injury (Berlowitz et al., 2005).

Many people living with SCI are prescribed medications (sedatives, muscle relaxants, and narcotics) that can affect breathing, especially during sleep. Loud snoring (a typical OSA sign) has been associated with the use of anti-spasticity medications and obesity in SCI in one cross-sectional study (Ayas et al., 2001). There have been no controlled studies in SCI of the effect of medication provision or withdrawal on SDB severity; however, a smaller proportion of those in the intervention (CPAP treatment for SDB) arm of the COSAQ study were prescribed baclofen at end-study (Berlowitz et al., 2019), and a non-significant reduction in baclofen prescription rates was observed in those whose SDB improved over time in another cohort trial (Berlowitz et al., 2005).

People with tetraplegia and those with lesions above T6, also develop increased nasal and total upper airway resistance due to increased parasympathetic tone. This increased nasal resistance may contribute to upper airway narrowing by increasing negative (collapsing) pressure in the upper airway during inspiration (Gainche et al., 2016; Wijesuriya et al., 2019). While this increased upper airway resistance can be acutely reduced with topical sympathomimetic application, no difference in SDB was observed in a pilot, cross-over randomized controlled trial of topical sympathomimetic application (phenylephrine) in people with tetraplegia and SDB (Wijesuriya et al., 2019).

Our research group in Melbourne, Australia and colleagues in Detroit, USA have undertaken the majority of these physiological sleep studies and both centers have used comparable physiological measures ensuring that our data are complementary. By comparing people with tetraplegia and SDB with control participants (no SCI) that had SDB, a number of putative physiological factors have been examined. The reflex response of genioglossus to negative upper airway pressure was reduced and delayed in people with both OSA and SCI compared to those with OSA but without SCI (Wijesuriya et al.,

2018). This reflex is an important protective response of the upper airway and a reduction predisposes the upper airway to collapse during sleep. The critical closing pressure of the upper airway (P_{CRIT}) is determined by first stabilizing the upper airway during sleep with small amounts of continuous positive airway pressure and then reducing that external pressure until the upper airway collapses. Sankari et al. demonstrated that the P_{CRIT} in tetraplegia and SDB is not different to non-disabled people with SDB (Sankari, Bascom, & Badr, 2014). Data examining arousal responses and muscle recruitment remain equivocal.

The upper airway is a collapsible tube where patency is largely dependent on the surrounding soft tissue, phasic and tonic muscle tone, fat pad volume, and extraluminal tissue pressure from blood, lymph, and extracellular water. A series of magnetic resonance imaging studies in people with SDB and tetraplegia have compared the structure and function of the upper airway with non-disabled controls and observed that while SCI OSA patients have heterogeneous pharyngeal dilator muscle responses to the negative pressures occurring during inspiration, as a group they are more similar to able-bodied OSA patients than healthy controls of similar age and BMI (Hatt et al., 2020; O'donoghue et al., 2018).

Clinical management of sleep-disordered breathing in people with SCI

Despite the high prevalence of SDB and its detrimental effects on health and quality of life, surveys indicate that less than 25% of people with SCI are diagnosed and treated for the disorder (Burns et al., 2001; Sankari et al., 2015). The "gold-standard" method for diagnosing SDB is a Level I, overnight, attended polysomnography (PSG). Clinical practice guidelines recommend PSG for people with SCI and signs and symptoms of SDB (Consortium for Spinal Cord Medicine, 2005). However, access to this test, which requires an overnight stay in a sleep laboratory, is often poor. At least two studies have investigated the use of limited channel studies to detect SDB in SCI with results demonstrating moderate accuracy of this less intensive method (Bauman et al., 2016; Graco et al., 2018). These limited channel sleep studies may provide alternatives to PSG, particularly when access to sleep specialist services is poor.

Treatments for SDB in SCI are essentially the same as for the general population. Continuous positive airway pressure (CPAP) is the first-line treatment for SDB. CPAP provides a continuous positive airway pressure of typically between 4 and 20 mmHg, via a mask, to prevent upper airway collapse during sleep. Our COSAQ study, described earlier, is the first and only controlled trial to investigate the effects of CPAP in people with SCI. It demonstrated that CPAP effectively improved daytime sleepiness in people with acute tetraplegia, although there was no effect of CPAP on neurocognition (Berlowitz et al., 2019). CPAP effectiveness is limited by poor adherence and acceptance of the therapy in both SCI and the general population. When defined as an average of at least 4 h per night, CPAP adherence in people with tetraplegia and SDB has been estimated at approximately 25% (Graco et al., 2019; Graco et al., 2019). A qualitative study seeking to understand the barriers and enablers to CPAP use among people with tetraplegia found that both the burdens and the benefits of using CPAP were substantial, and patients actively weighed these burdens and benefits to decide whether to continue with the therapy (Graco, Green, et al., 2019).

Other potential treatments for SDB in SCI include bi-level positive airway pressure (PAP), mandibular advancement splints (MAS) and positional therapy. Bi-level PAP is a more expensive PAP therapy than CPAP, which delivers a higher inspiratory than expiratory pressure and is commonly used for hypoventilation disorders. Some clinicians prefer to use it to treat SDB in patients with more severe SCI (i.e., high tetraplegia) and greater respiratory compromise, and in those with a predominance of central than obstructive events. However, there is no research evidence to support the use of bi-level PAP over CPAP for treating SDB in SCI, and vice-versa. MAS are commonly prescribed in the general population to those who are unable to tolerate CPAP or as a first-line therapy to treat mild OSA. The mouthguard-like device is worn on the upper and lower jaw and is designed to pull the lower jaw forwards to open the airway while simultaneously increasing tension in the soft tissues and preventing collapse. Research has demonstrated that MAS devices can effectively improve the symptoms of OSA in the general population (Iftikhar et al., 2017). As yet, there have been no published studies investigating MAS in SCI.

Recent qualitative research aiming to describe and understand the management of SDB in SCI rehabilitation centers has identified that the management of SDB is highly varied in SCI (Graco, Berlowitz, & Green, 2019). The most common management pathway for people with SCI suspected of having SDB involves referral from the primary care or rehabilitation doctor to a specialist sleep/respiratory physician for investigation and management (Graco, Berlowitz, & Green, 2019). However, this care model often presents significant access barriers to people with tetraplegia and may contribute to the low rates of detection and treatment seen in this population (Graco, Green, et al., 2019). The same study identified three spinal cord injury (SCI) rehabilitation centers that had developed an "in-house" SDB management model in response to poor access to specialist sleep services. In each center, a multi-disciplinary team provides screening, diagnosis and treatment of uncomplicated SDB using portable equipment and without direct specialist sleep service involvement. This

demonstrates that it is feasible for multi-disciplinary SCI rehabilitation teams to independently manage un-complicated SDB Graco, Berlowitz, & Green, 2019) and further research investigating the safety and effectiveness of SDB management provided by the rehabilitation team is urgently needed.

How does SCI alter the circadian rhythm?

Following a complete cervical SCI, afferent somatic and autonomic fiber pathways below the SCI are disrupted and the efferent sympathetic innervation of the pineal gland via the superior cervical ganglion is interrupted. This anatomical disruption alters the circadian rhythmicity of melatonin regulation and production in tetraplegia and those with paraplegia lesions associated with autonomic dysfunction, typically T6 and higher. Under normal conditions, light striking the retina stimulates afferent pathways through the suprachiasmatic nuclei (SCN) that in turn pass to the superior cervical ganglion and onward to the pineal gland to inhibit melatonin production. Darkness removes this inhibition, and melatonin is produced. The fibers from the SCN travel alongside those from the sympathetic system to exit the spine between the first and sixth thoracic levels. The SCN to pineal pathway then ascends *outside* the spinal canal to the superior cervical ganglion, back into the cortex, and on to innervate the pineal gland. This circuitous pathway exposes melatonin regulation to disruption after SCI (Fig. 4).

In 2000, Zeitzer et al. demonstrated that complete tetraplegia is associated with near abolition of circadian melatonin rhythmicity and a markedly reduction in circulating levels of the hormone (Zeitzer, Ayas, Shea, Brown, & Czeisler, 2000). The same authors also demonstrated that this dysrhythmia was specific to melatonin and did not extend to other circadian modified rhythms such as cortisol or thyroid stimulating hormone. Despite these clear abnormalities of circadian control in SCI and the ready availability of melatonin as a therapeutic, surprisingly little research has explored the clinical utility of exogenous melatonin after SCI. A small pilot study (Spong, Kennedy, Brown, Armstrong, & Berlowitz, 2013) and two small randomized controlled, cross-over trials have demonstrated that exogenous melatonin administration in tetraplegia is safe and appears to be associated with some subjective sleep improvement (Spong et al., 2013; Zeitzer, Ku, Ota, & Kiratli, 2014). Exogenous melatonin administration in tetraplegia has also been shown to normalize clock gene expression in

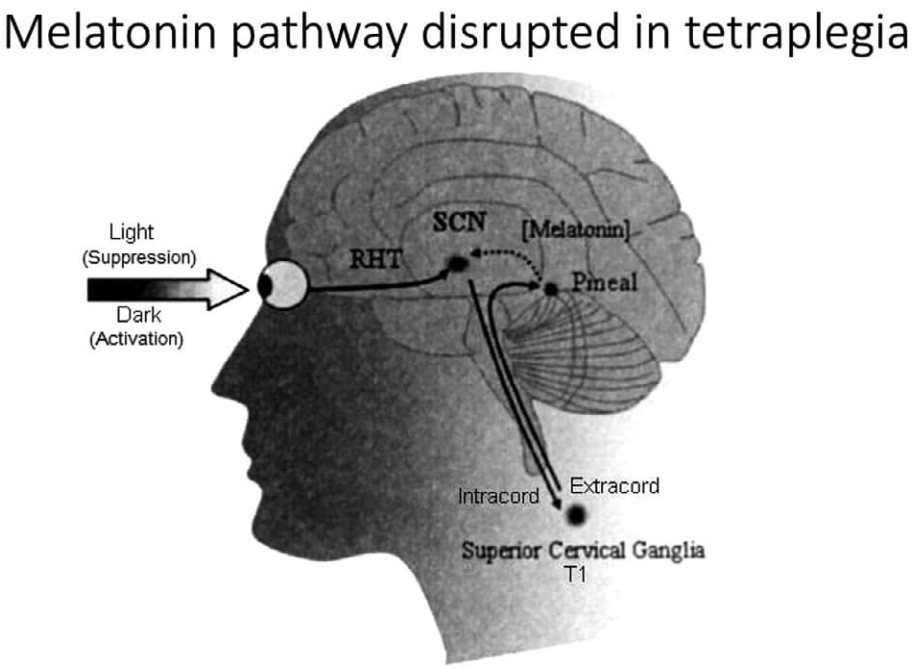

FIG. 4 Tetraplegia-associated interruption of Melatonin secretion. Light striking the retina stimulates the intrinsically photosensitive retinal ganglion cells which project monosynaptically, to the SCN via the optic nerve. The pathway continues to the superior cervical ganglion and onward to the pineal gland to inhibit melatonin production. Darkness removes this inhibition and thus melatonin is produced. The fibers from the SCN exit the spine between the first and sixth thoracic levels. The SCN to Pineal pathway then ascends outside the spinal canal to the superior cervical ganglion, back into the cortex, and on to innervate the pineal gland. A spinal cord injury above the first thoracic level will likely interrupt this pathway. *RHT* = retinohypothalamic tract. *SCN* = suprachiasmatic nuclei.

peripheral blood (Kostovski et al., 2015; Kostovski et al., 2018); however, the clinical significance of these findings is unclear.

Periodic leg movements of sleep in SCI

Periodic leg movements (PLM) are characterized by periodic episodes of repetitive and highly stereotyped limb movements during sleep. The associated restless leg syndrome (RLS) is characterized by uncomfortable leg sensations usually prior to sleep onset that causes an almost irresistible urge to move. Both conditions can result in considerable disruption to sleep quality and are typically associated with excessive daytime sleepiness. Up to 80% of RLS patients also experience PLMS (periodic leg movement syndrome), as defined by five or more PLM events per hour of sleep (Ferri et al., 2015). Periodic leg movement disorder (PLMD) appears to be another distinct sleep disorder that is more common in people living with SCI. The high prevalence of SDB in SCI, particularly in tetraplegia, confounds studies of PLMs because the AASM PLM scoring rules exclude events that occur from 0.5 s prior to or following a scored respiratory event. As such, co-existent SDB would theoretically tend to underestimate the severity of PLM, yet studies examining both SDB and PLM have consistently found an elevated rate of both. For example, Peters et al. reviewed 262 clinical and research sleep studies in people with tetraplegia and reported a SDB prevalence of 88% and a PLMD prevalence of 59% (PLMs per hour >15) (Peters et al., 2018).

While the precise etiology of PLMs in the general population is unclear, evidence of substantia nigra involvement and the clinical effectiveness of dopaminergic agents, has made them the mainstay of therapy and the belief that PLMs are centrally generated is the mainstream view. PLMs are predominantly observed in non-rapid eye movement (NREM) sleep in the general population whereas after SCI PLMs are apparent throughout sleep, including during rapid eye movement (REM) sleep. Indeed, PLMs have even been observed during wake after SCI (Peters et al., 2018). Interventions which alter cortical arousal in SCI do not necessarily result in a reduction in PLMs and similarly, inhibition of PLMs does not reduce sleep disruption (Manconi et al., 2012; Salminen et al., 2013). Taken together, these findings suggest that PLMs after SCI arise peripherally rather than centrally. Regardless of whether PLMs are a central and/or peripheral phenomenon in SCI, dopaminergic agents are still effective. A clinical case series of people with SCI referred for refractory "spasticity" despite maximal anti-spasticity therapy recently demonstrated that most in fact had untreated PLMs (Levy et al., 2018). Sleep studies demonstrated a substantial reduction in PLMs after pramipexole therapy.

Applications to other areas of neuroscience

In this chapter, we reviewed the prevalent sleep disorders in SCI, sleep-disordered breathing, circadian rhythm dysfunction, and periodic leg movements and examined the barriers to effective diagnosis and treatment. While all three disorders are well described in the non-injured population, the pathogenesis of these after SCI provides unique insights into the underlying neuroscience. It appears that tetraplegia is the only model of acute OSA in humans. As such, the comparative upper airway physiology experiments we detailed extend the phenotyping approach to understanding the individual personal determinants of the "end-organ dysfunction" we describe as OSA. In particular, differences in ventilatory control and afferent reflex activation in tetraplegia provide novel opportunities for exploration of neuropathophysiology. Similar to OSA, tetraplegia provides a unique model of disruption to the hypothalamic/melatonin/pineal axis of circadian control. Experiments such as those involving exogenous melatonin administration and light therapy with subsequent assaying of melatonin metabolism and peripheral clock gene expression will undoubtedly provide novel insights into neurohumoral circadian control, including in the non-injured. The periodic leg movement disorder had been characterized as a central dysfunction, with much of therapy focused on cortical dopaminergic augmentation. The high prevalence of PLMD after SCI refutes the "central-only" hypothesis and perhaps similarly to the OSA data, point to PLMD as another form of "end-organ dysfunction" with multiple phenotypic pathways to expression. SCI perhaps reveals pathogenic pathways not readily observable in the non-injured. Lastly, the examination of barriers to symptom recognition, diagnosis, and treatment of sleep disorders in SCI highlights issues that are likely common to other neurological and neuromuscular disorders such as stroke, multiple sclerosis, etc.

Mini-dictionary of terms

Periodic leg movements (PLM). These are periodic episodes of repetitive and highly stereotyped limb movements during sleep.

Restless leg syndrome (RLS). The RLS is associated with PLM and is characterized by uncomfortable leg sensations usually prior to sleep onset that causes an almost irresistible urge to move. Both PLM and RLS can co-exist in the same person and result in considerable disruption to sleep quality and subsequent excessive daytime sleepiness.

Circadian rhythm. The circadian rhythm is the natural, internal process that regulates the sleep–wake cycle, is regulated by the circadian clock and repeats roughly every 24 h.

Sleep-disordered breathing (SDB). SDB is an umbrella term representing a group of sleep disorders involving the respiratory system and characterized by repetitive periods of total or partial cessation of airflow during sleep.

Obstructive sleep apnea (OSA). OSA is a sub-category of SDB, characterized by repetitive periods of complete or partial obstruction of the upper airway during sleep resulting in complete or reduced airflow.

Central sleep apnea (CSA). CSA is another sub-category of SDB, characterized by the absence of respiratory effort at the time of complete/partial reduction in airflow.

Key facts of sleep

- Sleep is composed of four distinct stages. During normal sleep, a person cycles through these stages four to six times.
- We do most of our dreaming in REM (Rapid Eye Movement) sleep, which is Stage 4 sleep. REM sleep makes up between 20% and 25% of total sleep in healthy adults.
- During REM sleep all skeletal muscles, apart from the diaphragm and the ocular muscles, are essentially paralyzed.
- Teenagers move their circadian phase later in the day and need almost as much sleep as toddlers.
- Body temperature during sleep drops by half to one degree during sleep before rising again as we wake.
- The most common sleep disorders in humans are insomnia, sleep apnea, restless less syndrome and narcolepsy. It is estimated that 20%–40% of adults have a sleep disorder.

Summary points

- Acute cervical spinal cord injury results in sleep-disordered breathing.
- Sleep-disordered breathing in tetraplegia is predominately obstructive sleep apnea rather than central sleep apnea or hypoventilation.
- Acutely, obstructive sleep apnea impairs attention and information processing which improves over time; CPAP does not change recovery in neurocognitive function, but it improves sleepiness.
- Sleep-disordered breathing in tetraplegia is highly prevalent (83% mild, 59% moderate, and 36% severe).
- Sleep-disordered breathing in tetraplegia reduces health-related quality of life by approximately 30%.
- Obstructive sleep apnea in tetraplegia is not due to an upper airway that is smaller, more collapsible, or moves abnormally compared.
- The upper airway has a higher resistance in people with tetraplegia and OSA and that can be reduced, but larger studies are needed and phenylepherine is likely not to be the agent of choice.
- Melatonin supplementation may have subjective benefits.
- Translatable, novel treatment models of diagnosis and care for sleep disorders after SCI must be developed and tested for non-inferiority of person-centered outcomes.

VEGF	vascular endothelial growth factor

Introduction

Spinal cord injury (SCI) is a broad term that includes changeable grades of neurological deficits and is still considered an incurable condition. In spite of substantial advances in surgical and medical treatment, just around 1% of SCI patients experience complete healing. Unfortunately, almost 45% of the them suffer from serious neurological loss, which includes incomplete or complete tetraplegia, with or without respiratory compromise (Spinal Cord Injury (SCI), 2016). Therefore, SCI usually has devastating vocational, social, and physical implications for patients and caregivers (Ahuja et al., 2017).

The patient's outcome after initial SCI is still very difficult to predict, because the tools we have today for both evaluating the gravity of spinal cord tissue destruction and better assessing the recovery of SCI patients are still restricted (Rodrigues, Moura-Neto, & Spohr, 2018). Imaging examinations of the spinal cord cannot accurately predict the prognosis of the disease. Computed tomography shows only fractures or dislocations, while magnetic resonance imaging is not highly sensitive to edema of the spinal cord, be it related or not to SCI. Furthermore, laboratory tests of blood biochemistry such as lactate dehydrogenase and protein kinase C are not specific for SCI, as other non-neurological damage can also cause changes in blood parameters, having, therefore, no clinical application (Ding et al., 2019). There's no doubt that the sooner we evaluate the extent of the lesion and start treating the patient, the better the outcome is. Nowadays, the best predictive value of neurological assessment of the SCI patient is defined by typical clinical neurological examinations during the patient's first evaluation (Rodrigues et al., 2018). So the identification of biomarkers that can predict lesions is crucial to helping assess damage severity, prognosis, and therapeutic outcomes (Rodrigues et al., 2018).

In this chapter, we will highlight the most recent research on the expression of biomarkers in the pathophysiology of the SCI and try to correlate to diagnosis and prognosis.

Pathophysiology of SCI

It is well known that SCI occurs in two mechanisms that progress through three stages. Both mechanisms that lead to acute SCI are now very well characterized and recognized as primary (mechanical) and secondary injuries. The primary injury is caused by the initial mechanical trauma of surrounding tissues, followed by contusion and compression of the spinal cord, which induces damage to nerve cells, blood vessels, and myelin (Rodrigues et al., 2018). The secondary lesion is triggered by the primary lesion and is classified in three phases, namely the acute phase, the sub-acute (or intermediate) phase, and the chronic phase, according to the pathomechanism and post-injury time (Bareyre & Schwab, 2003; Rodrigues et al., 2018).

The acute stage begins with the mechanical injury and extends to the first 48 h after the initial traumatic injury. In this stage, the patient develops some neurological deficits directly associated with the mechanical injury. This is when innumerable pathophysiological processes begin, leading to the initial inflammatory response to the injury and causing patients to develop "spinal shock" (Albayar et al., 2019; Rodrigues et al., 2018). It is well established that, at this stage, crucial events are induced by vascular rupture, ischemia, and hemorrhage by the action of inflammatory growth factors which affects neurons and glial cells, including excessive production of free radicals, ionic dysregulation, inflammatory response, and excitotoxicity, inducing pathological changes (Kwon, Tetzlaff, Grauer, Beiner, & Vaccaro, 2004; Rodrigues et al., 2018). At this stage, primary care should be provided for the patients, including protection of the airways, maintenance of the respiratory function, and use of hemodynamic support (Albayar et al., 2019).

It is, however, often difficult to define the baseline severity of the injury, as the patient is often in an unstable clinical condition due to spinal shock (Hachisuka et al., 2014). In order to reduce inflammation and neurological deficits, some centers use high-dose corticosteroids in the first 8 h after the injury, following the NASCIS II protocol (Witiw & Fehlings, 2015). Nevertheless, damage to glial cells, neurons and oligodendrocytes caused by the presence of excessive amounts of excitatory neurotransmitters (glutamate, aspartate) cannot be prevented. Furthermore, neurons die during all phases of the injury due to necrosis and astrocytes. Neurons and oligodendrocytes also die due to apoptotic mechanisms (Beattie, Hermann, Rogers, & Bresnahan, 2002).

The secondary or sub-acute stage lasts up to 2 weeks after the damage. At this stage, the patient usually recovers from the initial spine shock. However, neurological loss as well as other potential complications associated with the original trauma continue, as nerve cell dysfunction and blood supply problems derived from the acute stage can get even worse

(Albayar et al., 2019). In this phase, reactive gliosis increases both the content of glial fibrillary-acidic protein (GFAP) and the size of astrocytes to form the glial scar, In this phase, an intense inflammatory response begins, whereby phagocytic cells are recruited (Bareyre & Schwab, 2003; Rodrigues et al., 2018). The glial scar, with its firmly fused processes, forms an inhibitory agglomerate in the form of a mesh that plays a fundamental role in interrupting axonal regeneration (Ahuja et al., 2017). However, despite limiting regeneration after an injury to the central nervous system (CNS), the uncontrolled proliferation of reactive astrocytes suppresses the formation of aberrant synapses at the injury site and also contributes to both the restoration of the integrity of the blood spinal cord barrier (BSCB) and the reconstruction of microenvironment homeostasis (Faulkner et al., 2004). This mechanism is important for the removal of edemas, in addition to reducing the infiltration of cells of the immune system, helping, thus to limit the spread of the lesion (Wanner et al., 2013).

The chronic SCI phase, whose characterization requires further investigation, follows the sub-acute SCI phase. At this stage, patients may experience partial neurological recovery, which will depend on the extent of the lesion and the general condition of each patient. In addition, patients may also have maturation of adaptive mechanisms or the onset of more delayed neurological symptoms such as urinary bladder dysfunction, neuropathic pain, lipodystrophy, musculoskeletal atrophy, dysautonomia, and abnormal skeletal postures (Eckert & Martin, 2017). This phase may prolong from days to years after the shock, and is characterized by Wallerian degeneration, apoptosis and scarring that cause functional impairment (Bareyre & Schwab, 2003; Rodrigues et al., 2018). At this stage, it is also normal for patients to develop **syringomyelia*** due to the formation of the glial scar. Therapeutic strategies generally focus on increasing the regeneration of damaged axons and remyelination through different mechanisms, whether through pharmacological methods or cell therapy (Kim, Ha, & Kim, 2017).

Biomarkers of SCI

First, it is important to define the word **biomarker***. Biomarkers, also known as "biological markers," are related to a wide sub-category of medical signs which can be measured with precision and reproducibility. Thus, biomarkers are, for purposes of interpretation, quantifiable results of biological mechanisms (Strimbu & Tavel, 2010). A biomarker of tissue injury should ideally be abundant, preferably (or exclusively) produced in the tissue of interest, and to be naturally present in small concentrations in blood and other body fluids (Laterza et al., 2009; Rodrigues et al., 2018). It is also important to have good biomarkers that can contribute as a measure of valuable therapeutic responses. They are highly valuable in the decision-making process of seeking additional clinical evaluation of a drug, and in helping to define critical parameters such as the intervention time window, drug dose and monitoring schedule for a clinical trial. It is also important to have good biomarkers that are acutely related to biochemical changes made or sustained during all phases of SCI. It is finally very important to validate all the potential biomarkers candidates.

Currently, there are neither drugs for treatment nor specific laboratory tests for the diagnosis of SCI. Therefore, in order to determine the extent of SCI as soon as possible, it is urgent to further the discovery and use of specific biomarkers for SCI. This could help guide doctors and researchers toward the discovery of a new object of intervention that can help prevent and decrease disability resulting from SCI.

SCI in the acute stage

In the acute stage, there is a change in the permeability of the BSCB, due to the formation of glial scarring and the disturbance of endothelial cells. These cells secrete various inflammatory cytokines and some are currently being investigated as potential SCI biomarkers. High concentrations of interleukin-6 (IL-6), interleukin-8 (IL-8), and monocyte chemotactic protein (MCP)-1 (also known as chemokine ligand 2 (CC motif) (CCL2)) have been expressed in CSF. They have been shown to be dependent on the severity of the injury, when patients presented with American Spinal Injury Association grade A (ASIA A) injury had higher levels of these cytokines compared to ASIA B and C patients (Kwon et al., 2010).

Recently, a study with 15 ASIA A and B patients demonstrated that IL-10, IL-1rα, IL-9, IL-16, and IL-18 were positively regulated 24 h after SCI, and that interferon-gamma (INF-γ) and IL-13 have been downregulated (Fernández et al., 2020). Upregulation of the high mobility group 1 box (HMGB1) and the inflammatory cytokine macrophage migration inhibitor (MIF) factor were also identified, both occurring regardless of the degree or severity of injury (Kwon et al., 2019). Several studies also analyzed the transient expression of some proteins during the acute phase. Some structural proteins in glial cells and neurons are usually modulated in the CSF and in the serum of patients with acute SCI. Proteins such as GFAP, Phosphorylated Neurofilament Heavy (pNF-H), light chains of neurofilaments (NFL, 68 kDa), neuron-specific

TABLE 1 Cytokines and proteins highly expressed in the acute stage.

Expression in CSF	Cytokines	Proteins
Upregulated	IL-6, IL-8, IL-10, IL-1rα, IL-9, IL-16, IL-18MCP-1 (CCL2), HMGB1, MIF	GFAP, S100β, NSE, p-NF-H, NFL, UCH-L1, SBDP, MBP
Downregulated	INF-γ, IL-13	

Table based on de Mello Rieder et al. (2019), Du et al. (2018), Fernández et al. (2020), Ghosh and Pal (2019), Kwon et al. (2019, 2010, 2017), Leister et al. (2020), and Moghieb et al. (2016).

enolase (NSE), glial-specific calcium-binding β protein (S100β), tau, ubiquitin carboxy-terminal hydrolase L1 (UCH-L1), αII spectrin breakdown products (SBDP), myelin basic protein (MBP), transferrin, cathepsin D, triosephosphate isomerase-1, and astrocytic phosphoprotein PEA-15 were analyzed in patients with acute SCI (de Mello Rieder et al., 2019; Du et al., 2018; Kwon et al., 2010, 2017; Leister et al., 2020).

GFAP is an astrocyte-specific intermediate filament protein associated with glial scar formation, and astrocyte protein S100β in adults is generally elevated due to damage to the nervous system. It has been shown that both GFAP and S100β are present at higher levels in CSF and serum 24 h after injury, depending on severity, and that both can serve as a prognostic biomarker (Kwon et al., 2017; Leister et al., 2020). Inverse results were observed with the tau protein, which is an intracellular neuron protein involved in the stabilization of microtubules. A negative correlation was observed between CSF and serum tau concentrations and the severity of spinal cord injury 24 h after the injury, suggesting that tau may score as a prognostic biomarker for neurological improvement after acute spinal cord injury (Kwon et al., 2010; Leister et al., 2020).

NSE, p-NF-H, NFL have been found to be elevated in the serum and CSF of patients with acute SCI. However, when p-NF-H decreases to normal values, it allows the prediction of a favorable outcome (Ghosh & Pal, 2019). UCH-L1, SBDP, MBP have also been found to be transiently elevated in the CSF of patients with SCI and show a correlation between severity and recovery (Moghieb et al., 2016) (see Table 1).

SCI in the sub-acute stage

In the sub-acute stage, during the formation of the **glial scar***, astrocytes increase the expression of not only GFAP, but also of nestin and vimentin. It has also been reported that, at this stage, astrocytes also secrete various **cytokines*** and growth factors such as vascular endothelial growth factor (VEGF), fibroblast growth factor (FGF)-β, glial cell-derived neurotrophic factor (GDNF), and growth factor transformer (TGF)-β, which are speculated to promote in later stages the differentiation, proliferation and migration of oligodendrocyte precursor cells. TGF-β1 is suggested to be implicated in scar formation after spinal cord injury (Kim et al., 2017; Rodrigues et al., 2018).

Recently, a study showed that patients with SCI had a decrease in both serum TGF-β1, an insulin-like growth factor 1 (IGF-1), and in sCD95L, but there was an upregulation 12 weeks after the injury correlated with the absence of neurological recovery (Ferbert et al., 2017).

CD95(Fas/APO-1)-ligand (CD95L) protein during the sub-acute phase is cleaved and a portion of it is released into the peripheral blood. This protein induces apoptosis in CD95-sensitive cells, especially at the sub-acute stages when apoptotic activity increases. This protein has the potential of acting as a biomarker at the sub-acute stage, and mainly of indicating the apoptotic effect destructive to the spinal cord tissue and the consequent neurological loss (Biglari et al., 2013). At this stage, the phagocytic inflammatory cells normally release cytokines that could be used as biomarkers. One of those cytokines is IL-1β, which has shown a significant fall at 1 and 4 weeks post injury in patients who experienced less progress (Biglari et al., 2015). Several metalloproteinases (MMPs) are upregulated during the sub-acute phase, and specially MMP-8 and -9, which have been pointed as a useful indicator for recovery potential (Albayar et al., 2019; Moghaddam et al., 2017). The C-X-C motif chemokine ligand 10 (IP-10) was found increased in serum at 3–6 h after SCI. However, there was a peak after 7 days of trauma at the sub-acute phase (Hassanshahi et al., 2013). Other proteins were pointed as potential biomarkers in the sub-acute phase, among them transferrin (TF), cathepsin D (CathD), triosephosphate isomerase-1 (TPI-1), phosphoprotein enriched in astrocytes 15 (PEA15), zinc alpha 2 glycoprotein (AZGP) and Haptoglobin (HP). They were found in human CSF from SCI patients, whose AZGP and HP protein levels decline in the CSF as the secondary injury process progresses (Moghieb et al., 2016; Sengupta et al., 2014) (see Table 2).

TABLE 2 MMPs, cytokines, proteins and growth factors highly expressed in the sub-acute stage.

Expression in CSF	Metalloproteinase	Proteins	Growth factors	Cytokines
Upregulated	MMP-8 and 9	Nestin, Vimentin, TF, CathD, TPI-1, PEA15	GFAP, VEGF, FGF-β, GDNF, TGF-β 1[a], IGF-1[a], CD95L[a]	IP-10
Downregulated		AZGP, HP		

[a]*Upregulation 12 weeks after the injury is correlated with the absence of neurological recovery.*
Table based on Albayar et al. (2019), Biglari et al. (2013, 2015), Ferbert et al. (2017), Hassanshahi et al. (2013), Kim et al. (2017), Moghaddam et al. (2017), Moghieb et al. (2016), Rodrigues et al. (2018), and Sengupta et al. (2014).

SCI in the chronic stage

During the chronic phase, glial cells and neurons continue to die from apoptosis, compromising the channel and the functions of the receptor, and scarring and demyelination accompany Wallerian degeneration. All of these processes lead to deficits and are signs that the injury has matured (Norenberg, Smith, & Marcillo, 2004; Rodrigues et al., 2018).

It has been shown that two potent pro-inflammatory cytokines, namely macrophage migration inhibiting factor (MIF) and high mobility group box 1 (HMGB1), which are present in large quantities in both types of immune and neuronal cells, were found increased in patients with chronic spinal cord injury, regardless of the severity or level of the injury (Kwon et al., 2019; Papatheodorou et al., 2017; Stein et al., 2013). Studies have also shown that, at this stage, patients have elevated levels of IL-2, tumor necrosis factor alpha (TNFα), C-reactive protein, IL-6 and interleukin-1 receptor antagonist (IL-1RA), the two latter also being related to urinary tract infections, neuropathic pain or comorbidities such as pressure ulcers (Davies, Hayes, & Dekaban, 2007; Frost, Roach, Kushner, & Schreiber, 2005; Kwon et al., 2019).

It has also been shown hat in the chronic phase there is an elevated expression of some autoimmunity-promoting cytokines such as B-cell maturation antigen (BCMA), B-cell activating factor (BAFF), and A proliferation-inducing ligand (APRIL), and that some proteins that were found elevated in acute SCI were also increasingly present in people with chronic SCI such as β2 microglobulin (B2M), enolase 2 (ENO2), and S100A9 (Saltzman et al., 2013; Streijger et al., 2018). These studies demonstrated that some biomarkers could be used as good candidates to evaluate biochemical changes made or sustained during all stages of the SCI in order to help validate the potential impact on the clinical care of patients throughout the treatment (see Table 3).

microRNAs as biomarkers

Recently, microRNAs (**miRNAs***) have been identified as good candidates as biomarker in blood in various pathologies, including in pancreatic adenocarcinomas, Alzheimer's disease, low-grade gliomas, ectopic pregnancy, breast cancer, and ovarian cancer among others (Rodrigues et al., 2018). The advantages of using miRNAs as biomarkers are that they are tissue specific, very stable in fluids, and have a phylogenetic relationship. In addition, they are present in all systems and have specific expression patterns at the developmental- and tissue-specific levels (Farh et al., 2005). MiRNAs downregulate the translation of RNA proteins by binding to the 3′-UTR of their target mRNAs. They are endogenously derived, short (usually 18–22 nucleotides in length), and generally induce mRNA degradation or translational repression (Bartel, 2004). The changes in the expression of miRNAs after SCI can be classified into three groups: (1) decreased miRNAs; (2) increased miRNAs; and (3) bidirectional (decreased or increased) miRNAs. There is little research related to miRNA and SCI in humans. Most of the studies have been conducted in rats, mice, or pigs. Efforts are currently being made to

validate in humans data that have been observed in animal models. There is no doubt that possible targets for modified miRNAs after SCI include genes that encode components involved in oxidative stress, inflammation, and apoptosis. The problem is that SCI patients represent very heterogeneous groups according to injury mechanism, severity and location, and the age and genetic background of the patients.

Recently, 190 detected miRNAs were found to be differentially expressed in the CSF of patients with all three SCI severities (ASIA A, B, and C). It was also demonstrated that these miRNAs showed changes in CSF and serum depending on the severity of the injury (Tigchelaar et al., 2019) (see Table 4).

Moreover, it was also shown that CSF miRNA expression at 24 h post injury within patients with ASIA A differs between those patients who will, and those who will not convert to ASIA B, and also differs from those that will not convert to C or D at 6 months post injury (Tigchelaar et al., 2019).

[a]*Table based on Tigchelaar et al. (2019).*

It was shown that a total of 19 miRNAs were differently expressed in human serum, and that 16 of them were specific only to the ASIA A group. The miRNA miR-133a-3p demonstrated the most significant change in expression, and it is already associated with injury severity. The miRNAs miR-208 and miR-499 associated with skeletal muscle mass regulation were demonstrated not only to be regulated in human serum after the SCI but also to have similar severity-dependent expression patterns (Boon et al., 2015; Tigchelaar et al., 2019).

However, the take-home message of the work from the group of Tigchelaar is that, although 190 miRNAs were detected in the CSF and 19 in serum after evaluating 44 individuals that met one of the three ASIA A, B and C criteria, only one of them, namely miR-423, was shown to be one of the strongest prognosticators of neurologic progress at 6 months post injury in humans (Tigchelaar et al., 2019). It is already known that miR-423 is related to neuronal apoptosis, as it regulates caspase-3 activity (Li et al., 2014).

Exosomes

Although "free circulating" miRNAs can be used as biomarkers, they have low concentration and little stability in other body fluids (Ding et al., 2019). Therefore, the best way to search for miRNAs is in the small extracellular vesicles (EVs) secreted by most of the eukaryotic cells, called exosomes.

Exosomes are EVs derived from the 30 to 120 nm endocytic membrane and are present in many or perhaps in all body fluids. They participate in cell-to-cell communication and distribution of proteins and RNA, as they transport a diversity of proteins, lipids and nucleic acids. Exosomal miRNAs in body fluids have many advantages over free miRNAs. It has already been shown that the molecular components of exosomes, especially exosomal proteins and miRNAs, are promising as new biomarkers for clinical diagnosis (Lin et al., 2015).

Recently, it was shown in a rat model of acute SCI that there were changes in the expression of miRNA in circulating exosomes associated with the pathological mechanism of acute SCI by their target-regulated pathways. Identified serum exosomal miR-130a-3p, miR-125b-5p, and miR-152-3p are distinguishing and easily detectable diagnostic markers in acute SCI. In the same study, other differently expressed miRNAs (DEmiRNAs) and their expression were found to be either up- or downregulated, depending on the activation or inhibition of signaling pathways with response to the injury (Ding et al., 2020) (see Tables 5 and 6).

TABLE 5 miRNAs identified in exosomes in acute SCI.

miRNA	Expression in SCI	Actions already known
miR-152-3p	Increased in the injured area after SCI	• Diagnosis, treatment, and prognosis of tumors • Dengue infection • Type 2 diabetic nephropathy • Alzheimer's disease
miR-130a-3p	Significantly increased in the SCI	• Regulate the insulin sensitivity and hepatic steatosis • Regulate cell migration and invasion in gemcitabine-resistant hepatoma cells • Suppress cell migration and invasion in human gastric carcinoma • Suppress cell viability, proliferation, and invasion in nasopharyngeal carcinoma • Increase cisplatin resistance in non-small-cell lung cancer • Regulate gemcitabine resistance in cholangiocarcinoma • Attenuate activation, and induces apoptosis of hepatic stellate cells
microRNA-125b	SIGNIFICANTLY decreased in the acute phase of SCI	• Significantly upregulated in primary glioblastomas • Highly expressed in mouse models of cardiac hypertrophy and idiopathic end-stage failing human hearts • Decreased in primary neuroblastoma tumors, psoriasis, and atopic eczema • Important negative regulator of p53 and p53-induced apoptosis

Table based on Ding et al. (2019, 2020) and Lin et al. (2015).

TABLE 6 DemiRNA targets that were identified in acute SCI.

Expression	Most enriched pathways of the targets of DEmiRNAs
Upregulated	• Axon guidance • Melanogenesis • Wnt signaling pathway • Long-term potentiation
Downregulated	• ECM receptor interaction • Focal adhesion

Table based on Ding et al. (2019, 2020) and Lin et al. (2015).

Conclusions

SCI can cause permanent disability, and yet, despite advances in clinical management, many patients are left with substantial neurological impairment. Presently, prevention is the only procedure we can take to avoid the primary mechanical damage to the spinal cord (Rodrigues et al., 2018). There is no doubt that these patients need to be correctly diagnosed, but an effective treatment for SCI hasn't been found yet.

The fact is that the sooner patients are treated and the magnitude of their lesion is defined, the better their chance of a good outcome. However, the problem of using proteins as biomarkers is that they should be frequently collected from the CSF in order to characterize the severity of the injury, but collecting CSF through a lumbar puncture is unquestionably invasive (Kwon et al., 2017; Rodrigues et al., 2018). Further bioinformatics analysis and functional research will be of great help in clarifying the role of exosomes, microRNAs and proteins in the pathological process of spinal cord injury and in judging whether they can be used as diagnostic markers (Ding et al., 2019). Unfortunately, the identification of biomarkers to predict SCI prognosis and treatment still needs much more research.

Applications to other areas of neuroscience

The research concerning the use of biomarkers as predictor for the treatment of SCI and several other devastating diseases such as cancer, cardiovascular diseases, Alzheimer's and Parkinson has been increasing since the last decade (Califf, 2018).

Recently, the search for good biomarkers has been focused on exosomal biomarkers, as they support comparable or superior sensitivity and specificity associated to their excellent stability (Lin et al., 2015). Using an animal model, it was demonstrated that urine exosomes may be a specific and sensitive source of miRNA biomarkers for experimental autoimmune encephalomyelitis (EAE) disease and Multiple Sclerosis (MS). It was possible to identify miRNAs in urine, plasma and spinal cord exosomes in a period before the onset of the disease, suggesting their early involvement in the pathology of EAE and MS (Singh, Deshpande, Suhail, Rattan, & Giri, 2016).

In addition to exosomal proteins and RNAs, exosomal lipids have also been shown to have a diagnostic potential. In patients with glioblastoma (GBM), several exosomes and miRNAs have been identified as being useful for diagnostic and/or prognostic biomarkers (Saadatpour et al., 2016). But unfortunately, exosomal biomarkers are still at an early stage of discovery/development and their potential value in clinical diagnosis has not been fully analyzed yet (Lin et al., 2015).

Mini-dictionary of terms

Biomarkers—Biomarkers, also known as "biological markers," are related to a wide sub-category of medical signs, which can be measured with precision and reproducibility. Therefore, biomarkers are often determined and evaluated to examine pathogenic processes, normal biological processes, or pharmacologic responses to a therapeutic intervention. In medicine, they can be used in clinical settings for guiding treatment based on their application: predictive, prognostic, or diagnostic.

Syringomyelia is an illness in which a cyst or cavity forms within the spinal cord. The cyst, also called a syrinx, can grow and become quite large over time, destroying the spinal cord. The damage may result in paralysis, loss of feeling, weakness, and rigidity in the shoulders, back, and extremities. The illness may also induce a loss of the ability to feel extremes of cold or hot, especially in the hands. It may also lead to a cape-like bilateral loss of temperature sensation and pain along the arms and upper chest.

miRNAs are small non-coding RNAs molecules containing about 22 nucleotide which are found in all species including plants, animals and some viruses. MiRNAs function in silencing and post-transcriptional regulation of gene expression, via base-pairing with complementary sequences within mRNA molecules. As a result, these mRNA molecules are silenced by one or more of the subsequent ways (1) cleavage of the mRNA strand into two pieces; (2) destabilization of the mRNA through shortening of its poly(A) tail, and (3) less efficient translation of the mRNA into proteins by ribosomes.

glial scar is formed by reactive astrocytes that proliferate and have processes that are firmly fused, making an inhibitory meshlike bundle that has the valuable task of acting as an obstacle for axonal regeneration, and therefore being considered the main origin for the restricted regeneration after a CNS damage.

Cytokines are a broad category of small proteins (~5–20 kDa) that are very important in cell signaling. They are peptides that cannot cross the lipid bilayer of cells to enter the cytoplasm, so they act through cell surface receptors and are especially important in the immune system. Cytokines can act in an autocrine, paracrine and endocrine fashion way. Cytokines include interleukins, chemokines, lymphokines, interferons, and tumor necrosis factors, but generally not hormones or growth factors (despite some overlap in the terminology). They are produced by a broad range of cells, including immune cells like macrophages, B lymphocytes, T lymphocytes and mast cells, as well as endothelial cells, fibroblasts, and various stromal cells. Cytokines are important in health and disease, specifically in host immune responses to inflammation, infection, cancer, trauma, sepsis, and reproduction.

Key facts of biomarkers spinal cord injury

- Spinal cord injury (SCI) is still considered an incurable condition, resulting in a heterogeneous recovery and an uncertain prognosis.
- The sooner patients are treated and the magnitude of their lesion is defined, the better their chance of a good outcome.
- Biomarkers, also known as "biological markers," are part of the biological response to injury, and are related to a wide sub-category of medical signs which can be measured with precision and reproducibility.
- Identification of biomarkers that can predict lesions is crucial to helping assess damage severity, prognosis, and therapeutic outcomes.
- Good biomarkers that can contribute as a measure of therapeutic responses are highly valuable in the decision-making process of seeking additional clinical evaluation of a drug, and in helping to define critical parameters such as the intervention time window, dose and monitoring schedule for a clinical trial.

Summary points

- Biomarkers are part of the biological response to injury.
- It is important to understand the degree or stage of the injury to focus on treatment.
- The change of proteins in some fluids is consistent, but their distribution in peripheral fluids is not the same.
- Non-invasive examinations with reproducible results are better to assess the injury.
- MiRNAs are tissue specific, very stable in fluids and have a phylogenetic relationship.
- Exosomes participate in cell-to-cell communication and the distribution of proteins and RNA, as they transport a diversity of proteins, nucleic acids and lipids.
- As exosomes are distributed in body fluids, exosomal miRNAs have many advantages over free miRNAs, being thus promising as new biomarkers for clinical diagnosis.

SF-36	Medical Outcomes Study 36-item short form health survey
SWLS	satisfaction with life scale
WHO	World Health Organization
WHOQOL	WHO quality of life instrument

Introduction

From the second half of the last century, advances in the study and medical care aimed to help people with spinal cord injury (SCI) have resulted in greater life expectancy in this population (Hill, Noonan, Sakakibara, & Miller, 2010). SCI sequelae are well known, as well as other specific associated medical problems that these patients have to overcome, which frequently interfere with everyday life. Likewise, people with SCI require specific equipment to enable the integration into their social and home environments and adapt to daily life, i.e., from mobility devices to incontinence products, as well as help from other people for basic activities of daily living (ADL). All these circumstances cause great psychological pressure with which they have to live and result in comorbidities, e.g., anxiety, depression, distortion of body image, self-esteem, sense of failure, etc.

Moreover, there are different barriers that interfere particularly with the quality of life (QOL) of people with disabilities (Bökel et al., 2020). In 2001, after various periods of study and reflection on models for evaluating people with distinct functional capabilities, the World Health Organization (WHO) developed the International Classification of Functioning (ICF) (WHO: https://apps.who.int/iris/handle/10665/42407) that addresses the medical condition from a biopsychosocial perspective and seeks to integrate a person's functional capacity with the execution of activities and social participation (Dijkers, 2005).

Diagnosis and Treatment of Spinal Cord Injury. https://doi.org/10.1016/B978-0-12-822498-4.00014-2

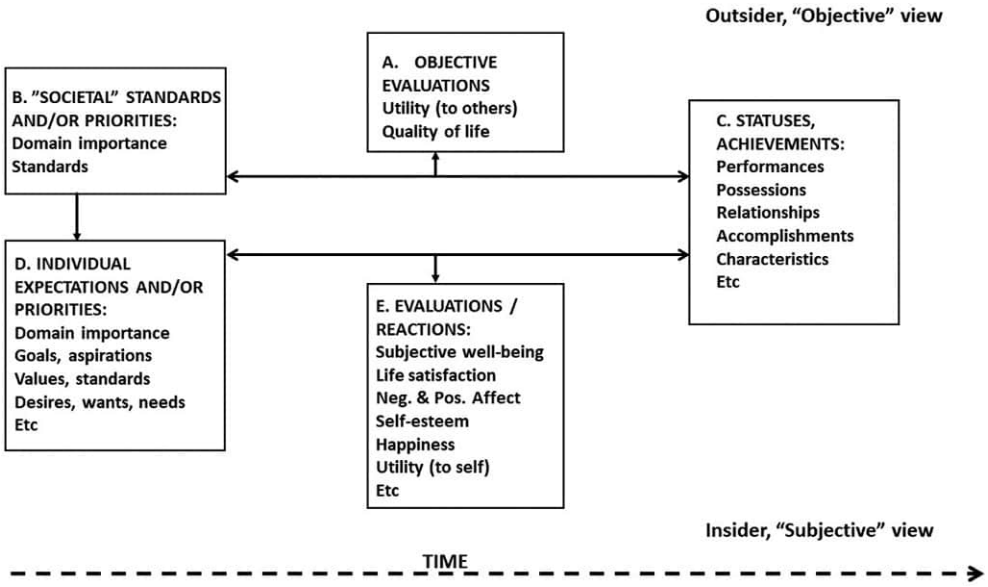

FIG. 1 Dijkers' Model of approach to quality of life. Approach to quality of life according to a "objective" or "Subjective" view, which shows various factors that influence the researcher's perception in their social environment, or the individual's and their subjective standards. *(With permission from: Dijkers MP. (2003) Individualization in quality of life measurement: instruments and approaches. Arch Phys Med Rehabil,84 Suppl 2: Fig. 1, page S4.).*

However, despite the work done, there is no agreement in the scientific literature on the concept of QOL to be studied in handicapped people and/or with chronic diseases, as in the case of this population (Hill et al., 2010; Post, 2014). In their assessment, researchers additionally need to define the concept of health, which affects the daily life of the people subject of study.

Since the establishment of the concept of *health* by the WHO in 1947, "*a state of complete physical, mental and social well-being and not merely the absence of disease or infirmity*", QOL was correlated to states of subjective well-being, although later, some objective aspects were included (Post, 2014).

Thus, the definition of *quality of life* in medicine and in psychology has been the subject of controversy on many occasions. On the one hand, a subjective approach is adopted by the person subject of study, in which there should be a consistency between the person's expectations and achievements to perceive satisfaction in their lives. On the other hand, there is an objective approach in which case the observer establishes certain parameters that characterize a satisfactory QOL from different points of view (Dijkers, 2003) (Fig. 1) one of them being the medical condition considered by the researcher (Hill et al., 2010; Miller et al., 2010).

If we consider the previously exposed ideas, different angles can be used when assessing QOL in people with SCL: subjective assessment of QOL by the person (Moons, Budts, & De Geest, 2006), its interrelation with the social environment in which the person lives, physical components—mainly impairments due to physical sequelae—mood, overall health status, or by specifying the difficulties in the management or assumption of system dysfunction that affect having a satisfactory social life—family-related, work-related, and education.

Definitions: Quality of life and health-related quality of life

QOL is a multi-dimensional concept that includes subjective and objective factors, for which reason it is defined differently in each academic field, social group, or individuals. In fact, the WHO defines QOL as "*individual's perception of their position in life in the context of the culture and value system in which they live and in relation to their goals, expectations, standards, and concerns*" (The WHOQOL Group, 1998). This conveys a subjective view linked to the social context.

For an integrative assessment of QOL, an approach from a variable number of dimensions or *domains* is accepted, each of which refers to an area of vital aspects that differs from the others (Dijkers, 2005). To complete the definition of *health* proposed by the WHO, at least three dimensions are included: physical function, mental state, and ability to have social interactions (Post, 2014), which are usually found in the instruments that measure QOL from a subjective view by the affected person and the objective perspective of the observer.

Thus, approaching QOL in medicine is easily associated with the concept of health-related quality of life (HRQOL), which according to Dijkers is part of an objective view and makes reference to *those components in the person's QOL directly or indirectly affected by the disease, lesions, and treatment side effects* (Dijkers, 1997), for which reason the "medical condition" of the person is included, as pointed out by Post (2014).

On a higher level, the interaction of the health domains with the ability to interact with the surroundings and function of the person is contemplated in the structure of the ICF (Post & Noreau, 2005).

Implementation in the study of quality of life in people with spinal cord injury

Defining the concept of QOL and its assessment from an objective view is subject of discussion and lack of agreement between researches (Tate & Forchheimer, 2014), due to the complexity of SCI physical sequelae, along with the outcome of rehabilitation and evidence that people with SCI may enjoy a full life integrated in their social environment. The instruments are usually developed based on values imposed on the participants, and sometimes there is little relation between the values communicated by the concerned individuals and those believed to be relevant by the researches and even by the caregivers (Fuhrer, Rintala, Hart, Clearman, & Young, 1992). As stated by Tate (Tate, Kalpakjian, & Forchheimer, 2002), subjects affected by SCI distinguish between having spinal cord injury–related sequelae and their health status ("I am healthy").

For this reason, the impact certain sequelae have on various QOL domains is examined in instruments assessing HRQOL in people with SCI-related sequelae, along with the assessment of global QOL, the latter form a subjective view as it can only be determined by the affected person (Moons et al., 2006).

Databases

There are numerous academic institutions and knowledge bases trying to cluster the different instruments for measuring abilities, sequelae, or dysfunctions, and their interaction with the subject's life regarding physical aspects, function, mental, social, and of QOL in general. Concerning SCI, the SCIRE project (Miller et al., 2010; www.scireproject.com) is of great relevance. Revisions of the different fields of action are carried out in the project, and recommendations of different assessment instruments given, with regular updates, reviews on their validity, and diffusion in the medical literature. Likewise, numerous instruments for assessing health conditions secondary to SCI are found in the resources grouped in the Participation and Quality of Life Toolkit (ParQOL; www.parQOL.com), but in this case, they are related with Dijkers's QOL model and provide use and access instructions.

From a perspective focused on the person, the project developed under the auspice of the National Institutes of Health in the United States of America as of 2004, the Patient-Reported Outcomes Measurement Information System (PROMIS: www.healthmeasures.net), groups numerous useful instruments for assessing different elements linked with HRQOL that have shown a correlation with aspects collected by the ICF (Wong et al., 2018). The mission of PROMIS is to create a health model to transmit the health status communicated by the subject (Post, 2014), so that a global assessment on the person that is useful for the observer can be made compatible with the standards of the ICF. Its use in subjects with neurological disorders concentrates in Neuro-QOL (Tulsky et al., 2015). A specific HRQOL for SCI is the SCI-QOL, inside the PROMIS project, that is undergoing validation with a large sample of persons with SCI in United States of America (Tate & Forchheimer, 2014).

However, the use of many instruments is complex in clinical practice, and consequently clinical researches focus on a limited number of them. When choosing a tool, we must consider which is the aspect of QOL we want to assess: the subjective perspective of the person, the relationship with the social and cultural environment, specific health domains, effect of a specific sequelae or dysfunction, comparison or not with other populations—either by cultural setting or different type of disability or function—specific validation for SCI or general, etc. (Geyh, Fellinghauer, Kirchberger, & Post, 2010; Tate & Forchheimer, 2014).

Several reviews of the instruments and methods used for assessing QOL in people with SCI have been done (Hill et al., 2010) (Tables 1 and 2).

Below we discuss the most commonly used instruments in the medical literature, clustering them as global QOL and specific HRQOL for certain SCI-related sequelae tools (Tables 3 and 4). Despite the numerous instruments used in this population, there are no agreed standard measures and some show deficiencies in validity and sensitivity to change in comparative studies.

TABLE 1 Objective QOL Instruments.

Objective tools									
Name	**Description**	**Items**	**Domains (No. of questions)**	**Scoring and response**	**Measurement model**	**Time taken (min)**	**Alternative languages**	**Item bias**	**Interviewer (I) or self-administration**
Patient reported impact of spasticity measure (PRISM)	Addresses negative and positive impact of spasticity on QOL in SCI population	41	Societal avoidance/ anxiety (11); psychological agitation (5); daily activities (6); need for assistance/ positioning (5); impact on activities +/− (4); need for intervention (5); social embarrassment (5)	5-point Likert scale Sub-scale scores are obtained by averaging item scores and dividing by number of items Higher is unhealthier	"Relative to the range of the scale, more persons scored in lower ranges (indicating less impact)"	Not available	None	Developed in SCI population	SA
Quality of well-being questionnaire-SA (QWB-SA)	Point-in-time preference measure designed to measure HRQOL	71	Symptoms and problems (58); mobility, physical activity, social activity (13)	0.0—death to 1.0—optimum health Higher is healthier	No floor and ceiling effects	<20	Various	Face validity supports low bias	SA
Qualiveen	Disease-specific perspective on QOL in SCI for urinary disorders	30	Limitations (9); constraints (8); fears (8); feelings (5)	5-point Likert scales (0–4); total range 0–100 Tabulate total Higher is unhealthier	Minimal	Not available	Various	Developed in SCI population	I or SA
Sickness Impact Profile (SIP68)	Generic health status measure, measures health-related changes in behavior associated with the carrying out of daily activities	68	Somatic autonomy (17); mobility control (12); mobility range (10); social behavior (12); emotional stability (6); psychological autonomy and communication (11)	No = 0, yes = 1; total range 0–68 Yes responses are tabulated; can divide into SIPSOM, SIPPSY, SIPSOC sub-scales Higher is unhealthier	Ceiling effects MR (31.3%), ES (54%), & PAC (53.8%) domains	~15–20	Dutch	Scoring on one question adjusted for SCI	I or SA

Short Form 36 (SF-36)	Addresses basic human values relevant to QOL and well-being through individual domains and two global components	36	Physical functioning (10); role limitations because of physical health problems (4); bodily pain (2); general health (5); vitality (4); social functioning (2); role limitations because of emotional problems (3); mental health (5)	Total range 0–100 Norm-based score is 50, with standard deviation 10. Can be divided into two summary scores: physical and mental, calculated by a system of + and − weights on domain scores Higher is healthier	Floor and ceiling effect PF (12.2%–24.2%; free—29.7%), RLP (28.1%–36.3%; 22.5%–54.4%); ceiling effect SF (free—33.5%), RLE (63.8%–75.3%)	<15	Available in most major languages	Face validity supports low bias	I or SA
Short form 36 veterans/SCI (SF-36 V)	Version of SF-36 designed for use in the disabled population. Physical functioning section has been modified to accommodate SCI population	36	Physical functioning (8)	Each domain converted to range of 0–100 Divided into two summary scores: physical and mental components, are norm based; general population score 50 and standard deviation of 10 Higher is healthier	"Descriptive responses to the items showed a floor effect on many of the items"	Not Available	None	PF domain altered in SCI population	I or SA
Short form 12 (SF-12)	A shortened version of the SF-36, used in population studies	12	Physical functioning (2); role limitations because of physical health problems (2); bodily pain (1); general health (1); vitality (1); social functioning (1); role limitations because of emotional problems (2);	Total range 0–100 Divided into two summary scores: physical and mental components, are norm based; general population score 50 and standard	Summary scores free of floor and ceiling effects	˜2–4	Available in most major languages	Face validity supports low bias	I or SA

Specific instruments that are used for measuring the impact of some conditions in the QOL of the person. The author that spread it is displayed. Abbreviations: PRISM, Patient Reported Impact of Spasticity Measure; SCI-SET, Spinal Cord Injury Spasticity Evaluation Tool; BPI, Pain Brief Inventory; MPI, Multi-dimensional Pain Inventory; MPRCQ2, Multi-dimensional Pain Readiness to Change Questionnaire; WUSPI, Wheelchair Users Shoulder Pain Index; NBDS, Neurogenic Bowel Dysfunction Score; FIQOL, Fecal Incontinence Quality of Life Scale; FICQOL, Fecal Incontinence and Constipation Quality of Life; SIAS, Sexual Interest, Activity and Satisfaction; FSFI, Female Sexual Function Index; IIEF, International Index of Erectile Function.

There are also many other tools for evaluating different aspects of people with SCI in relation with their QOL, as measures of health status, physical function, mental function, and participation. We display some examples of tools referenced in the literature that are useful in SCI population studies (Table 5).

Integrative quality of life assessment instruments

The **Medical Outcomes Study 36-Item Short Form Health Survey (SF-36)** was developed in the early 90s (Ware Jr. & Sherbourne, 1992). It is a generic scale that provides a profile of the health status (physical and mental components) and has been useful for assessing HRQOL in the general population and also in people with SCI. This scale has been validated and used in several languages and a short version of the SF-36 has been constructed (SF12) with similar validity (Iorio-Morin et al., 2018). However, all the above-mentioned is not an impediment to point out there are certain difficulties for its use in SCI persons, as some of the items are not easy to apply in this population due to mobility issues (Andresen, Gravitt, Aydelotte, & Podgorski, 1999; Tate et al., 2002) and modifications were done adapted to this objective, either by reformulating the items (Froehlich-Grobe, Andresen, Caburnay, & White, 2008) or adapting new items to the disability (SF-36 V) (Kazis et al., 2004; Luther et al., 2006). Nonetheless, it is one of the most widely used reference instruments,

TABLE 5 General instruments referenced for SCI assessments.

Instrument	Measure	Assessing	Refer to

DASS-21	Mental function	Screening for depression, anxiety and stress	Mitchell MC et al. 2008 https://maic.qld.gov.au/wp-content/uploads/2016/07/DASS-21.pdf
SCL CSQ	Mental function & general	Three domains about coping with SCI: acceptance of injury, social reliance and fighting spirit	Elfström ML et al. 2007 http://scireproject.com/wp-content/uploads/Clinician-Summary-v.5.0_SCL_CSQ.pdf

There are several measurement instruments used in combination to QOL scales. Some representative tools are displayed, with the author that spread it. Inside the PROMIS-NEURO-QoL system, there are several measures that are useful in many function and health domains. Healthmeasures.net is referred for obtaining them. Abbreviations: CHART, Craig Handicap Assessment and Reporting Technique; FIM, Functional Independence Measurement; SCIM-III, Spinal Cord Independence Measurement v.III; DASS-21, Depression Anxiety Stress Scale; SCLCSQ, Spinal Cord Lesion-related Coping Strategies Questionnaire.

with high consistency and reproducibility. It measures the following domains: physical, mental, emotional, pain, vitality, social functioning, and health in general.

The **Quality of Life Index** (QLI) has been widely used since its proposal by Ferrans and Powers and has been adapted to SCI (May & Warren, 2002). It allows assessing general QOL with social, spiritual, and economic aspects, and has been applied to SCI populations (Mortenson, Noreau, & Miller, 2010), associated or not to other objective instruments, e.g., assessment of bladder dysfunction (Best, Ethans, Craven, Noreau, & Hitzig, 2017). It is available in numerous languages and thus very useful to evaluate this population, although its psychometric properties have not been completely established in SCI (Miller et al., 2010).

Another known instrument for global assessment is the **Satisfaction with Life Scale** (SWLS) (Pavot & Diener, 1993), validated for people with SCI (Dijkers, 1999) and widely used in different studies in subjects with SCI (Post, van Leeuwen, van Koppenhagen, & de Groot, 2012), including assessment of rehabilitation outcomes (Hicks et al., 2005). This tool is

recommended for its shortness (five items) and easy-to-use in daily clinical practice; it has an acceptable consistency and reliability for comparative studies (Miller et al., 2010). Despite its wide use, larger psychometric studies should be performed in subjects with SCI (Geyh et al., 2010).

The **Life Satisfaction Questionnaire** (LISAT) developed by Fugl-Meyer in 1991, has been applied in several studies, mainly European, in its nine-item version, showing correct validity in relation with other QOL instruments (Post & Noreau, 2005; M. W. Post et al., 2012) and correct internal consistency (Geyh et al., 2010). However, its use in assessment studies with the SCI population is scarce.

The **Quality of Well-Being** (QWB) scale was used in numerous studies since its development by Andresen in 1998. Later, the self-administered version (QWB-SA) was created. However, this is an instrument with a high number of items (71) and there are few references on its validity in people with SCI (Andresen et al., 1999; Whitehurst, Engel, & Bryan, 2014).

During the decade of the 90s the WHO Quality of Life group developed the research of instruments for assessing QOL (The WHOQOL Group, 1998) in people affected by diverse conditions (AIDS, mental disorders, cancer, transplant recipients, etc.). Thus, in 1995 the **WHOQOL-100** questionnaire was created, and later its reduced version—the **WHOQOL-BREF—**was created (https://www.who.int/mental_health/publications/whoqol/en/). It has been applied on people with SCI since 2004 (Jang, Hsieh, Wang, & Wu, 2004) and validated in different languages, together with the 26-item short version. This version (WHOQOL-BREF) has demonstrated good applicability in clinical diagnosis with sufficient psychometric characteristics, although some of its domains (social) have less consistency due to the low number of items (Skevington, Lotfy, & O'Connell, 2004). Many validation studies against other reference instruments such as the SF-36 have been carried out (Lin, Hwang, Chen, & Chiu, 2007), showing lower ceiling and floor percentages. Similarly, in general, its items are better accepted by people with SCI than the SF-36. Its validity for studying global QOL and its relationship with physical, psychological, and relation with the surroundings, makes it interesting for studying the QOL in people with SCI-related sequelae (Salvador-De La Barrera et al., 2018).

In the early 90s, the European EuroQol-Group (1990) developed an instrument for measuring HRQOL. Five assessment domains were established: mobility, daily activities and self-care, psychological functioning, social and role performance, and pain or other health problems. Furthermore, a grading of global QOL was added in the form of a visual analogue scale (VAS) (Devlin & Brooks, 2017). This instrument began to be widely used and two versions were made: the **EQ-5D** and the **EQ-3D** that differentiate in the number of levels that characterize each domain, based on the levels of difficulty or affectation (five or three degrees, respectively). The EuroQol instrument has been widely used, translated into several languages, and applied to people with SCI; however, it has not been sufficiently validated for this population, with the disadvantage that mobility items are drafted incorrectly for wheelchair users (Whitehurst, Noonan, Dvorak, & Bryan, 2012).

Health-related quality of life assessment instruments for conditions resulting from spinal cord injury

Numerous instruments have been proposed to assess the effects the different sequelae and dysfunctions caused by devices have on QOL in people with SCI. Give the diversity of scales and instruments it is not possible to discuss all of them (Table 4). We have selected a sample of the most referenced ones in the medical literature, e.g., assessment of the impact of conditions such as bladder dysfunction, pain, spasticity, or sexual function.

- Assessment of the impact of neurogenic bladder on the quality of life of patients with spinal cord injury

The Qualiveen-30 questionnaire was developed by Costa (Costa et al., 2001) to specifically measure the impact of bladder dysfunction on QOL in spinal cord-injured patients. It is a 30-item subjective questionnaire comprising four domains, each considering different aspects derived from alterations in bladder emptying (limitations, constraints, fears, and feelings).

The validity of the questionnaire in patients with SCI has been tested in many studies (Bonniaud, Bryant, Parratte, & Guyatt, 2008a; Nikfallah et al., 2015) and stands out for its high reproducibility and internal consistency (Nikfallah et al., 2015). Furthermore, the questionnaire has been validated by comparing it to other QOL questionnaires, such as the Kings Health Questionnaire (Karapolat, Akkoç, Eyigör, & Tanıgör, 2018). The use of the Qualiveen-30 questionnaire has been extended to other medical specialties, e.g., multiple sclerosis (Milinis, Tennant, A Young, & Group, 2017).

In 2008, the short version of this questionnaire was developed, the SF-Qualiveen (Bonniaud et al., 2008a), with eight items and four domains.

Recently published reviews recommend Qualiveen-30 and SF-Qualiveen and identify them as the best options to assess the QOL in people suffering from neurogenic bladder after SCI (Best et al., 2017).

- Assessment of the impact of spasticity on the quality of life of people with spinal cord injury

Spasticity is a common impairment associated to SCI and considered a limiting factor by many patients (Levi, Hultling, Nash, & Seiger, 1995). To date, few scales are available for patients with SCI. However, in a systematic review carried out by Balioussis (Balioussis, Hitzig, Flett, Noreau, & Craven, 2014), the authors concluded that the Patient-Reported Impact of Spasticity Measure (PRISM) is superior to the Spasticity Evaluation Tool (SCI-SET), because besides including more psychometric data, PRISM is more sensitive for measuring the impact of spasticity and represents more affective values.

PRISM is a subjective scale developed by Cook (Cook et al., 2007), a 41-item tool divided into seven sub-scales. Currently it is only available in English and Serbian, has good reliability and reproducibility (Hill et al., 2010), and has been validated for patients with multiple sclerosis (Knezevic et al., 2015). Several studies support the usefulness of this measuring tool (Hill et al., 2010; Sweatman, Heinemann, Furbish, & Field-Fote, 2020; Whitehurst et al., 2012).

- Assessment of the impact of pain on the quality of life of patients with spinal cord injury

Although exact prevalence of chronic pain in patients with SCI is variable, this condition is considered a major limiting factor, causing huge impact on QOL (van Gorp, Kessels, Joosten, van Kleef, & Patijn, 2015).

The **Brief Pain Inventory (BPI)** is an instrument designed to assess the severity of pain and its impact on ADL. It was shaped based on McGill's pain questionnaire, translated to several languages, and may be completed as a self-report or interview (Cleeland & Ryan, 1994). This instrument is available in two formats: the BPI short (used for clinical trials and translations to other languages) and long (with additional descriptive items) forms (de Andrés Ares et al., 2015).

There are three modified versions of this inventory for the SCI population (7, 10, and 12 items). Five additional items make up the 12-item scale (self-care, recreational activities, social activities, communication, learning new information) and only the first three ones are used to complete the 10-item scale. Its clinical use has been confirmed in different studies (Dawu et al., 2019; Hand, Velozo, & Krause, 2018).

Regarding its reliability, internal consistency of the BPI is high for the three modified versions and as for the validity, it has high correlation with pain intensity numerical rating scales and with the Short Form-36 (SF-36) scale (Raichle, Osborne, Jensen, & Cardenas, 2006).

- Assessment of the impact on sexual dysfunction

Preserving sexual function is one of the high priority issues of subjects after SCI. Subjective scales were developed at the end of the 80s and early 90s to assess QOL associated to sexual function (The SCIRE Project; https://scireproject.com/outcome-measures/). However, in the systematic review carried out by Abrahmson (Abramson, McBride, Konnyu, Elliott, & Team, 2008) the authors pointed out that none of the scales have the ability to assess the most relevant aspects that define sexual health of this population group. On the same line are the recently published ISCOS guidelines, which establish the recommendations on data collection when analysis of sexual function is done segregated by gender: International SCI Male Sexual Function Basic Data Set and the International SCI Female Sexual and Reproduction Function Basic Data Set (Alexander et al., 2017).

At present, the most widely used sexual function scales in people with SCI are the International Index of Erectile Function (IIEF) and the Female Sexual Function Index (FSFI), although neither one is sufficiently validated in patients with spinal cord injury (S. Elliott & Querée, 2018) and cannot be considered QOL assessment instruments. Recently (2019), a questionnaire within the SCI-High Project has been developed—the SCI-High Sexual Health Patient Questionnaire—and is pending validation (S. Elliott et al., 2019).

Finally, it is important to point out the need for widely used, validated, and accepted instruments, and we support the initiative of the International SCI Data Sets Project of the international societies ASIA and ISCOS (Biering-Sørensen et al., 2006; Tate & Forchheimer, 2014). Although the SCI-QOL-Basic Data Set (QOL-BDS) questionnaire (Charlifue et al., 2012) is not widely distributed and there is scarce experience, it has shown sufficient consistency for its use in studies and data collection databases (Post et al., 2019).

Conclusions

When assessing the QOL of people with SCI-related sequelae, the subjective view of the person must always be taken into consideration, choosing the instrument as per the global or specific aspect to be studied.

Global QOL assessment instruments are the most widely used covering many domains linked to the medical condition of the person. When studying HRQOL, an objective approach is done defining the domains possibly affected by SCI, without putting aside the subjective perspective of the person.

The use of instruments focused on a specific SCI-related condition or sequelae should be based on wide studies. Furthermore, there must be agreements for their validity in many social and cultural environments.

Applications to other areas of neuroscience

Assessment of quality of life (QOL) in handicapped people is part of the rehabilitation and measurement of outcomes. In the case of spinal cord injuries (SCI), sequelae resulting from the lesion or disease affect the person's live and measuring instruments are essential. Simultaneously, the consequences on the person's psychological sphere have an effect on the subjective component. Thus, many of the studies performed to assess these instruments belong to the field of psychology.

On the other hand, major advances have been made on the knowledge and treatment of SCI-related sequelae, although their impact on QOL and acceptance by the affected subject, have not always been sufficiently assessed, e.g., the different alternatives for the management of bladder dysfunction (Best et al., 2017). Thus, the use of instruments that measure health-related QOL, when studying outcomes of new therapeutic methods for chronic sequelae, is of great importance.

Similarly, measuring QOL is recommended after rehabilitation and when using new therapies aimed at motor recovery (Hicks et al., 2005), such as robotic systems for walking and technical help for mobility, whose integration into daily life may affect his/her perspective of QOL. This assessment will also be of great help to show the advances of neurobiological therapies of spinal cord injury.

Usually, global QOL instruments are not specific for SCI and have been adapted to diverse neurological pathologies, which allow their comparison in many populations. Instruments that are specific for SCI are usually validated for subjects with multiple sclerosis (Bonniaud, Bryant, Parratte, & Guyatt, 2008b), among other conditions.

Finally, we reiterate the need of international validation and agreement regarding the instruments (D. Tate & Forchheimer, 2014), as this will allow making comparisons between diverse cultures and conditions.

Dictionary of terms

Quality of life (QOL): Individual's perception of their position in life in the context of the culture and value systems in which they live and in relation to their goals, expectations, standards and concerns.

Health: a state of complete physical, mental and social well-being and not merely the absence of disease or infirmity.

Health-related quality of life (HRQOL): Those aspects of QOL that are affected by the state of physical or mental health.

Disability: an umbrella term, covering impairments, activity limitations and participation restrictions, reflecting an interaction between features of a person's body and features of the society in which he or she lives.

Functioning: is a term that denotes the positive aspects of the interaction between a person's health—body structures and their limitations—and his contextual (environmental and personal) factors.

Domain: is an area of knowledge, emotions, or abilities, which are distinguished from others, being measured or examined by a test.

Spasticity: disordered sensory-motor control, resulting from an upper motor neuron lesion, presenting as intermittent or sustained involuntary activation of muscle.

Neuropathic pain: Pain caused by a lesion or disease of the somatosensory nervous system.

Neurogenic bladder: abnormal or difficult function of the bladder, urethra, sphincter system in mature individuals, in the context of clinically confirmed relevant neurologic disorder.

Validity: ability of the instrument to measure the construct that it intends to measure and for which it was designed.

Key facts of measuring quality of life in sci people

- Quality of life (QOL) is a subjective multi-dimensional concept that may be assessed with instruments not specific for people with spinal cord injuries (SCI).
- There is no universal agreement on the assessment of QOL in this population.
- For assessing the impact of SCI-related sequelae on the person's QOL, instruments aiming objective measures are used (Health-related QOL [HRQOL] instruments).
- Instruments for objective measurements of HRQOL must also include items for a subjective assessment of QOL by the person.
- Multi-center agreements should be reached regarding the numerous HRQOL measuring instruments to achieve greater diffusion.

Summary

- Spinal cord injuries–related sequelae lead to a series of daily difficulties for the affected person that may further hinder his/her quality of life.
- Quality of life (QOL) is a *subjective* concept defined as "*individual's perception of their position in life in the context of the culture and value system in which they live and in relation to their goals, expectations, standards, and concerns*."
- QOL may be viewed from a subjective perspective by the affected person or objective by the observer, then including QOL aspects affected by the disease or lesion (health-related quality of live—HRQOL).
- Global QOL questionnaires, such as WHOQOL, SWLS, QLI, SF-36, and EuroQol, are the most commonly used assessment tools.
- Specific instruments to assess the impact that certain conditions associated to spinal cord injuries (SCI) have on QOL have been developed, e.g., bladder dysfunction, spasticity, as well as others adapted from other populations, such as neuropathic pain and sexual dysfunction.
- It is important to establish international agreements regarding the use of validated instruments that can be compared in diverse populations for measuring different aspects of QOL in people with SCI.

Chapter 15

S100b in spinal cord injury

Andreas Zigouris, Georgios Kafritsas, George A. Alexiou, and Spyridon Voulgaris
Department of Neurosurgery, University Hospital of Ioannina, Ioannina, Greece

List of abbreviations

CSF cerebrospinal fluid
SCI spinal cord injury
MRI magnetic resonance imaging
CNS central nervous system
MS multiple sclerosis

Introduction

Spinal cord injury (SCI) results in severe social–economic problems, because it is observed mostly among younger adults. The incidence of SCI has been reported at 10.5 cases per 100,000 people (Kumar, Lim, Mekary, et al., 2018). This type of injury occurs in young to middle-aged populations due to road traffic accidents, violence, and contact sports. Unfortunately, only 1% of SCI patients experience injuries that fully resolve. Almost half of cases suffer of severe neurological loss (para/tetraparesis, para/tetraplegia) with or without respiratory disturbances (Albayar, Roche, Swiatkowski, et al., 2019).

Several prognostic factors have been proposed according to the previously published studies. But there is still no consensus on which clinical diagnostic tests could be applied to reliably indicate the sub-clinical neurophysiological changes occurring in the spinal cord during the acute phase, and this affects the prediction of cell death and tissue destruction in SCI. Neurological examination provide a general indication of spinal cord neurological function, but are unreliable, especially during the acute phase (first 24 h) after SCI as a result of spinal shock in many patients (Cao, Yang, Liu, et al., 2008). MRI provides an accurate anatomical diagnosis, but it is impossible to distinguish neuronal tissue necrosis from post-traumatic edema. Most of the medical decisions are targeting the stabilization of the patients and preventing further injury, but no definitive treatment for the present state of the CNS trauma exists (Albayar et al., 2019). In these cases, where the real-time injury is the question in clinical diagnosis and prognosis, serum and CSF biomarker evaluation provides another option. A biomarker must be accurate, sensitive, specific, and provide high predictive value. The most widely used biomarker in such cases is S100b, a protein found in cells of neural crest derivation, which can be measured in the serum after disruption of the blood brain barrier (Wolf, Krall, Pajenda, et al., 2014, b). S100b is implicated in a very broad number of CNS conditions, and as such, it is perhaps one of the strongest candidate markers (Sen and Belli, 2007). In case of a CNS injury, accompanied by a nervous tissue and cellular damage, this structural protein is released from nervous cells and its concentration increase extra-cellularly—including CSF and blood. In these cases, S100b could be a potential biomarker of nervous tissue damage (Hajduková, Sobek, Prchalová, et al., 2015).

S100b characteristics

The S-100 protein family constitutes a sub-group of Ca^{+2}-binding proteins. The term "S-100" was used because this protein was soluble in 100% ammonium sulfate and refers to a mixture of dimeric proteins consisting of two sub-units termed α and β (Sen and Belli, 2007). Three isoforms are known. S100a (αβ) is found in glial cells and melanocytes, S-100b (ββ) is present in high concentrations in glial cells and Schwann cells of the central and peripheral nervous systems as well as in Langerhans cells and cells of the anterior pituitary gland and S-100a0 (αα), which represents 5% of the S-100 protein in the brain (hippocampus, olfactory cells). The last is found outside the nervous system in slow-twitch muscle, heart, and kidney (Donato, 1991). The genes encoding the majority of human S100 proteins are organized in a cluster within the

Diagnosis and Treatment of Spinal Cord Injury. https://doi.org/10.1016/B978-0-12-822498-4.00015-4

chromosomal region 1q21, while some genes coding individual S100 proteins are located in other chromosomal regions, including 21q22 where, in particular, the gene for the S100b protein is located (Michetti, Corvino, Geloso, et al., 2012).

S100b is primarily an astrocytic protein and it was first detected in CSF at the acute phase of exacerbation of MS (Michetti et al., 2012). The majority of astrocytic S100b is located within the cytoplasm, 5%–7% is membrane bound. At least 80%–90% of the total S100b pool is found within the brain, the remainder being located in other non-neuronal tissues. S100b is thought to be involved in a number of Ca^{+2}-dependent cellular functions, including protein phosphorylation, enzyme activation, cell proliferation and differentiation, cytoskeletal dynamics, intra-cellular Ca^{+2} homeostasis and protection against oxidative injury (Donato, 1991). In a low concentration it seems to have a neurotrophic effect, it stimulates the growth of neurons, and it increases their survival during development and also during an injury. Higher concentrations might be toxic and evoke cell death. S100b is metabolized and excreted by the kidneys and has a half-life of about 30 min. S100b is found at low levels in healthy patients and remains chemically stable for several hours after sampling (Donato, 1991, 2003).

S100b and CNS pathology

S100b was regarded for almost two decades as specific to the nervous system (Michetti et al., 2012). Generally, S100b acts like a damage-associated molecular pattern (DAMP), which is released from damaged or activated cells under conditions of cell stress. Furthermore, a more complex role of S100b in the inflammatory processes has been described (Hajduková, Sobek, Prchalová, et al., 2015).

The concept of brain-specific proteins was first proposed in 1965 when S100 was characterized by Moore as a neuronal protein (Moore, 1965). Many studies followed this conclusion and found a clear role of S100b protein in maintenance and development of CNS. This role of S100b protein could be summarized in the following points (Donato, 1991, 2003):

- Regulation of enzymatic activities
- Interactions with cytoskeleton proteins
- Stimulation of neuronal differentiation, neurite extension activity, and pro-survival effects on neurons
- Protection of p53 from thermal denaturation and aggregation; stimulation of p53-dependent cell growth arrest and apoptosis (tumor-suppressor activity); inhibition of p53-dependent transcription activation (tumor-promoting activity) via disruption of the p53 tetramer
- Stimulation of astrocyte proliferation and apoptosis
- Stimulation of IL-6 secretion by neurons, NO secretion by astrocytes and microglia
- Modulation of synaptic plasticity

Over the years, different studies observed a varied grade of correlation between S100b overexpression in neuropathologic states in vivo and trophic/toxic effects in vitro. For example, overexpression of S100b protein has also been shown in cerebral palsy, Gilles de la Tourette syndrome, Down syndrome, Alzheimer's disease, schizophrenia, cerebral vasospasm after subarachnoid hemorrhage, astrocytomas, after head injury, and Creutzfeldt–Jacob disease (Sen and Belli, 2007). S100b protein could also represent a useful tool for early detection of intra-ventricular hemorrhage in the post-asphyxia period when clinical examination and cranial ultrasound might still be silent. It is reasonable to hypothesize that S100b accumulates in the extracellular space after astrocyte death or due to increased release by activated astrocytes, or after cellular disintegration of the damaged parenchyma. The finding that increased S100b is not accompanied by alterations in other structural markers of neural cell types, such as glial fibrillary acidic protein (GFAP), myelin basic protein (MBP) and neuron-specific enolase (NSE) has been regarded as an indication that S100b is actively released by astrocytes rather than leaked from damaged cells (Michetti et al., 2012). Under these conditions, the increased accumulation of S100b may become toxic due to its stimulatory effects on nitric oxide production by astrocytes and microglia (Sen and Belli, 2007).

S100b is normally present in cells derived from the neural crest but also from chondrocytes, adipocytes, myoepithelial cells, macrophages, Langerhans cells, dendritic cells, and keratinocytes (Benneker, Leitner, Martinolli, et al., 2008). Additionally, many studies have suggested extra-cranial sources of S100b, such as following cardiopulmonary bypass surgery, cardiac arrest, carbon monoxide and benzodiazepine poisoning, small and large bone fractures, abdominal injuries, and in fat tissue (Wolf, Krall, Pajenda, et al., 2014, b). Although in trauma patients larger extra-cranial soft tissue and bone injuries led also to an increase of S100b, confounding the interpretation of results, studies focused only on TBI cases revealed a high negative predictive power of S100b. They have found S100b elevation in CSF and peripheral blood after TBI, which is positively correlated with the severity of injury but negatively correlated with outcome. It was concluded that monitoring of S100b levels could contribute to early detection of patients at risk of secondary rises in intra-cranial pressure and subsequent fatal outcome (Sen and Belli, 2007).

Biomarkers in SCI

The acute phase of SCI is evaluated by neurological examination and MRI study. These patients are classified based on image characteristics, severity and need for surgical intervention. In comparison with MRI, neurological findings are most predictive of outcome. As the degree and localization of injured and spared white matter primarily determine functioning after SCI, MRI has limited success as a prognostic tool (Leister, Haider, Mattiassich, et al., 2020). On the other hand, injury severity alone does not adequately predict the degree of spontaneous neurological recovery.

Spinal cord trauma causes an acute disruption of the spinal cord parenchyma, which is followed by a secondary axonal degeneration and further degeneration or death of nerve cells by either apoptosis or necrosis, processes that may last from days to weeks. As the spinal cord is surrounded by vessels and CSF, damage to the spinal cord releases proteins and metabolites from the nervous tissue into CSF and blood. The implementation of biomarkers in SCI provides a useful tool supporting clinical decision making in acute SCI, especially in severe injured unresponsive patients (Guez, Hildingsson, Rosengren, et al., 2003; Leister et al., 2020).

An ideal prognostic CNS biomarker should have all of the following properties: CNS specificity, rapid and profound release into blood or/and CSF after injury, easily assessed, predictability of serious injury from an early sample, correlation of biomarker value with injury severity, of low cost minimally influenced by other factors and reproducible (Vaage and Anderson, 2001). The most studied biomarkers for SCI patients and their characteristics are summarized in Table 1.

TABLE 1 Characteristics of most studied biomarkers.

Biomarkers	Characteristics
Neurofilament proteins ✓ NF-L (light) ✓ NF-M (medium) ✓ NF-H (heavy)	• Components of neuronal cytoskeleton • Control axonal signaling and transport • Increase extra-cellular concentration upon neurological injuries • NF-L correlated with severity of SCI and neurological outcome
Glia fibrillary protein (GFAP)	• Components of astrocytic cytoskeleton • Development of astrocytic cytoskeleton • Variable CSF levels according to type of spinal injury • Post-traumatic CSF levels correlated with motor improvement
Cleaved Tau protein (C-Tau)	• Axonal microtubules • Stabilization of cytoskeleton • Axonal transport • Doubtful role
S100b protein	• Calcium-binding protein in astrocytes • Homeostatic balance • Regulating calcium levels, cell proliferation and differentiation • Enzymatic and metabolic • Early increase correlated with severity of SCI and outcome
Neuron-specific enolase (NSE)	• Neuronal cytoplasm enzyme • Homeostatic balance • Intra-lesional levels increased in experimental studies • Early increase correlated with severity of SCI and outcome
MAP-2 (microtubule-associated protein 2)	• Cytoskeletal proteins enriched in dendritic cells • Determining and stabilizing neuronal morphology during neuron development • Rapid loss post injury in experimental studies
Myelin basic protein	• Myelin sheath • In rat models post-traumatic detection in regenerated oligodendrocytes and marked increase in CSF, serum and intra-lesionally
Matrix metalloproteinases (MMPs)	• Extra-cellular matrix • Cell migration • CNS repair • Post-traumatic increase, in sub-acute phase correlated with outcome

TABLE 2 Characteristics of most studied inflammatory biomarkers.

Inflammatory biomarkers	Characteristics
Transforming growth factor beta (TGF-β)	• Regulation axonal extension, astrogliosis, and proteoglycans' accumulation • After 12 weeks there was a correlation between the increased levels and the poor neurological improvement
Tumor necrosis factor-alpha (TNF-α)	• Released within a few hours after damage • In 12 weeks post-injury CSF and serum levels correlated with neurological outcome
Insulin-like growth factor (IGF)	• In 12 weeks post-injury higher serum value is correlated with worse neurological improvement
Interleukins (ILs)	• Inflammatory process and glial scar tissue formation after SCI • At first and fourth post-traumatic week decreased serum levels of IL-1B in patients with poorer neurological status
Soluble CD95 ligand (sCD95L)	• Upregulation responsible for apoptosis in oligodendrocytes and spinal cord neurons • Increased serum levels during the sub-acute phase

SCI is a well-known neuroinflammatory process starting with local ischemia and edema. In cellular level, ionic disturbances and mitochondrial dysfunction have been observed. These events lead to neuron death, disruption of blood-brain barrier (BBB), neutrophils and macrophages infiltration and finally scar formation into the spinal cord (Albayar et al., 2019). Based on this concept several inflammatory biomarkers were also studied from several authors as specific predictive tool in cases of SCI (Biglari, Swing, Child, et al., 2015; Ferbert, Child, Graeser, et al., 2017) (Table 2).

S100b and SCI

The last 20 years there are several experimental and in vitro studies about the predictive role of S100b in tissue, serum or CSF after SCI, concluded that this biomarker could be a real-time indicator of early stages of spinal cord involvement (Table 3).

TABLE 3 Studies of the last 20 years about the role of S100b in SCI.

Study	Experimental/ Human	Biological fluid	Results
Ma, Novikov, Karlsson, et al. (2001)	Rats	Serum	At 3, 12, and 72 h after SCI increased levels were identified
Cornefjord, Nyberg, Rosengren, et al. (2004)	Pigs	CSF	Non-significant differences were identified after the induced nerve root injury
Loy, Sroufe, Pelt, et al. (2005)	Rats	Serum	At 6 h after SCI increased levels
Cao et al. (2008)	Rats	Serum, CSF	At 2 h after SCI serum and CSF concentrations were elevated
Schultke, Griebel, and Juurlink (2010)	Rats	Serum	At 6, 12, and 24 h after the trauma S-100b levels were significantly higher in quercetin-treated animals
Kwon, Stammers, Belanger, et al. (2010)	Human	CSF, serum	The highest levels during the first 24 h were included in the final prediction model
Ersahin, Toklu, Erzik, et al. (2011)	Rats	Serum	Significant increase 1 week after SCI induction
Zhang, Huang, Su, et al. (2011)	Pigs	CSF, serum	S-100B was significantly increased in the serum and cerebrospinal fluid 3 h after trauma

TABLE 3 Studies of the last 20 years about the role of S100b in SCI—cont'd

Study	Experimental/ Human	Biological fluid	Results
Pouw, Kwon, Verbeek, et al. (2014)	Human	CSF	The mean S-100β concentration in motor complete patients was significantly higher compared with motor incomplete patients
Wolf, Krall, Pajenda, et al. (2014, 2014b)	Human	Serum	Patients with neurologic deficits had significantly higher S100b levels compared with the patients with vertebral fractures but without neurologic deficits within 24 h after injury
Dalkilic, Fallah, Noonan, et al. (2018)	Human	CSF	Significantly lower in patients, who experienced an improvement within 6 months after injury
Yang, Bramlett, Moghieb, et al. (2017)	Rats	CSF, serum	Significantly elevated levels within 24 h (acute phase)
Kwon, Streijger, Fallah, et al. (2017	Human	CSF	Motor score improvement also was strongly correlated with the 24-h post-injury CSF levels
Du, Li, Sun, et al. (2018)	Human	Serum	Levels rose after the injury and reached a peak on the fourth day of injury, which was followed by a gradual decline 2 weeks after the injury

The initial experimental approaches found high level of S100b in the first 3–6 h in CSF and serum, whereas in some other cases was recorded an increase even at 3–7 days after SCI (Cornefjord et al., 2004; Ersahin et al., 2011; Loy et al., 2005; Ma, Novikov, Karlsson, et al., 2001). An experimental study from Cao, Yang, Liu, et al., 2008 showed significantly elevated serum and CSF levels of S100b and NSE which were then considered to be the most specific biomarkers for the acute phase of SCI (Cao et al., 2008). Their data indicated that NSE and S100b protein level changes are time-dependent and correlated with higher neurological defects and injury severity. A significant increase in NSE and S100b protein levels in serum and CSF was observed at 2 h after injury, and in a stepwise manner they reached maximum levels at 6 h. Serum S100b levels were elevated as well as 24 h after SCI as it was observed from Schultke et al. (2010). In general, S-100b protein levels in animals' serum and CSF elevate following SCI and have diagnostic value. During the initial 6 h of SCI, the level of this protein is very high in CSF and serum, but with time passing, the serum level of this protein decreases and after 24 h, its rate does not differ from animals without SCI (Faridaalee and Khajeh, 2019). Marquardt et al. found that the serum levels of S100b in rats rose rapidly within a short time (24 h) and then declined gradually and reached the normal level around the 10th day of injury, an observation similar to study from Marquardt, Setzer, and Seifert (2006) and Zhang, Underwood, Landfield, et al. (2000).

S100b was studied as a predictor of initial spinal cord damage that reflects directly to the severity of SCI. Kwon et al. studied in vitro the correlation between elevation in IL-6, IL-8, MCP-1, Tau-Protein, S100b, and GFAP and severity of injury (Kwon et al., 2010). Using protein concentrations at 24 h post injury, the model accurately predicted the observed ASIA grade in 89% of patients and furthermore provided a better prediction of segmental motor recovery at 6 months post injury than the patients' baseline ASIA grade. In a CSF study of 16 SCI patients Pouw et al. found that mean levels of S100b were significantly higher in more severely injured patients according to ASIA scale, reinforcing the aforementioned findings of Pouw et al. (2014). Protein levels were comparable between males and females, and not associated with age which gives rise for a more objective assessment despite the heterogeneity in patients with SCI. Marquardt et al. observed also that S100b could have a predictive value in other cases of spinal cord pathology. Patients with epidural empyema and persistently increased S100b levels for a minimum of 3 days after operative decompression had unfavorable functional outcome, as measured by motor function. Patients with spinal metastasis and persistently increased S100b levels for a minimum of 10 days after operative decompression had unfavorable functional outcome, as measured by motor function (Marquardt, Setzer, & Seifert et al., 2004a, 2004b). Marquardt concluded that the only significant biomarker correlation was between S100b serum levels and fractures of the vertebral spine, as well as between S100b serum levels and spinal cord injuries with resulting neurological deficits. Animals with favorable outcome had either always normal levels or levels that were initially increased but normalized within 2 days, when the values of animals with unfavorable outcome were elevated throughout (Marquardt, Setzer, Theisen, et al., 2011). Du et al. found that S100b has a sensitivity of 71.79% and a specificity of 66.67% for the evaluation of neurologic functional recovery (Du et al., 2018). The cut-off value of 29.07 μg/L indicated that patients with more than this value had increased risk of poor prognosis. Serum levels were low

in the well-recovered group but very high in the modest-recovered group. Patients' recovery was mainly associated with the extent of SCI damage at the time of injury. The serum levels of S100b increased after injury and reached a peak on the 4th day of injury. Then, the levels declined gradually, 2 weeks after the injury. Elevated S100b in human CSF after SCI was observed in patients with worse neurological outcome and lower concentration in cases of significant improvement after 6 months in a study from Dalkilic et al., when Kwon et al. reported a strong correlation between motor score improvement and CSF level of S100b in the first 24 h (Dalkilic, Fallah, Noonan, et al., 2018; Kwon et al., 2017). In the same year, an experimental study confirmed that highest levels of S100b in serum and CSF appeared in acute post-traumatic period (Yang et al., 2017).

Significant S100b serum level changes were seen in patients with vertebral spine fractures and spinal cord injury. When spinal fracture occurs, the fractured vertebrae affect the adjacent spinal cord which is a bundle of neurons, and S100b is then released from the injured spinal cord. A percentage of 5%–15% of cases with significant cervical injuries is missed on plain radiographs though were high-risk patients (Pouw, Hosman, van Middendorp, et al., 2009). CT or MRI is recommended in high-energy injuries and in patients with normal plain radiographs but continued symptoms. On the other hand, as it was reported in previous studies, there is a "false positive" range of biomarker elevations because it was observed that patients with a period of aortic clamping and patients with a whiplash trauma may have elevated biomarker levels in CSF without neurologic deficits. S100b can play a significant role in determining whether further evaluation is needed for patients with normal plain radiographs of spine even in absence of neurologic deficits (Pouw et al., 2009). Markedly increased levels of S100b in patients with spinal fracture might be evidence of spinal cord injury (Lee, Kim, Lee, et al., 2010). In a study of 19 patients with isolated vertebral fractures, Benneker detected elevated S100b serum levels, with a mean S100b value of 0.38 μg/L. Benneker concluded that the measurement of S100b serum levels has a high negative predictive power to rule out vertebral fractures (Benneker et al., 2008). In another study from Wolf et al. (S100b) serum levels was significantly higher in patients with vertebral spine fractures and additional presence of neurological deficits was correlated significantly with higher S100b serum levels (Wolf, Krall, Pajenda, et al., 2014, b).

Limitations and perspectives

S100b protein could be a useful tool after SCI for early detection of the degree of spinal cord involvement and the grade of neurological outcome within a 6-month period. The presence of extra-cranial injuries where fat and bone tissue are involved contributes to elevated S100b in serum and may be over interpreted as a reliable positive predictor for injuries to the spine (Albayar et al., 2019; Benneker et al., 2008). Additionally, before the 72 h post-injury period, factors such as spinal shock and medical instability affect the reliability of the neurological examination (Pouw et al., 2014; Zhang et al., 2011). Noteworthy that there is a severe difficulty to obtain CSF sample from SCI patients as it is painful and is associated with a risk of epidural hematoma that may lead to further spinal cord compression.

The most recent study from Leister et al. included series of clinical trials, cohort studies, pilot studies based on the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) statement and consists a detailed report for biomarkers in SCI (Leister et al., 2020). The correlation between S100b and severity of spinal cord injury according to neurological outcome could raise considerations for future respective studies such as:

- Correlation with later time imaging findings may reveal new pathways between structural changes and fluctuations of biomarkers (Zhang et al., 2011).
- Biomarkers that could be related with short and long-term complications after SCI, when there are at least 10 times more chronic SCI patients than new SCI cases (Albayar et al., 2019; Yousefifard, Sarveazad, Babahajian, et al., 2019).
- Use the protein not only as a biomarker but also as a potential therapeutic target for treatment of the pathological conditions in which it is involved (Sen and Belli, 2007).
- Increased knowledge about mechanisms of regulation of post-injury S100b release (Donato, 1991, 2003; Michetti et al., 2012).

Applications to other areas of neuroscience

- When the patient suffers from TBI, the blood-brain barrier is disrupted, causing a leakage of proteins from the CSF with subsequent cerebral edema formation.
- The most studied protein biomarker of cerebral damage in TBI is S100b.
- All traumatic cerebral injuries have been shown to have increased S100b in serum, but focal injuries, such as cerebral contusions and subdural hematomas, present higher levels as compared to diffuse injuries.

- Patients without a steady decline of S100b in CSF and serum have been shown to present with worse outcome.
- S100b appears to be an important and useful predictor of functional outcome in moderate-to-severe TBI.

Mini-dictionary of terms

- ***S100 protein***: Family of low-molecular-weight proteins with two calcium-binding sites and are involved in a variety of intra-cellular and extra-cellular functions.
- ***Spinal cord injury***: Traumatic damage to the spinal cord with or without bone and ligament involvement.
- ***Traumatic brain injury***: An alteration in normal brain function caused by an external force.
- ***Biomarker***: A measurable indicator of a medical condition which is evaluated using sample of blood, urine, CSF or soft tissue.
- ***Blood-brain barrier***: A barrier between capillaries (small blood vessels) and other components of brain and spinal cord (parenchyma, meninges, bone) that protects them from pathogens and toxins.

Key facts of calcium-binding proteins

- Calcium in nervous system is involved in functions membrane excitability, signal transduction, neurotransmitters release, synaptic plasticity, cell-cycle regulation, cell migration, and axon growing.
- Calcium-binding proteins react to Ca^{2+} transients and modulate the activity of proteins involved in both maintaining homeostatic conditions.
- Calmodulin, parvalbumin, calbindin, S100 proteins, calpain, and more than 200 proteins belong to this family.
- S100b protein has been measured in CSF and blood of patients with cerebral infarction, transient ischemic attack, hemorrhage, and head injury.
- S100b might be a selective biomarker to estimate the extent of nervous tissue damage and the prognosis of patients after SCI.

Summary points

- Spinal cord injury (SCI) results in severe social-economic problems, because it is observed mostly among younger adults.
- Most of the medical decisions are targeting the stabilization of the patients and preventing further injury, but no definitive treatment for the present state of the CNS trauma exists.
- In these cases, where the real-time injury is the requested in clinical diagnosis and prognosis, serum and CSF biomarker examination provides a quantitative method.
- As the spinal cord is surrounded by vessels and CSF, damage to the spinal cord releases proteins and metabolites from the nervous tissue into CSF and blood. The implementation of biomarkers in SCI provides a useful tool supporting clinical decision making in acute SCI.
- S100b constitutes was regarded for almost two decades as specific to the nervous system.
- The last 20 years there are several experimental and in vitro studies about the predictive role of S100b in tissue, serum or CSF after SCI, concluded that this biomarker could be a real-time indicator of early stages of spinal cord involvement.

MMT	manual muscle testing
SCI/D	spinal cord injury or disease
SWAT	Standing and Walking Assessment Tool
WheelCon	Wheelchair Use Confidence Scale v.3

Introduction

Following spinal cord injury or disease (SCI/D), physical rehabilitation is focused on regaining independence for community living and maximizing quality of life. The multi-disciplinary rehabilitation team facilitates the retraining of daily activities (e.g., bathing, feeding) and mobility (e.g., walking, wheeling, transferring), and assists with the reintegration of vocational and recreational activities. The priorities of rehabilitation are also informed by people living with SCI/D, who have identified improving upper limb and trunk strength, sexual function, bowel and bladder function, and walking ability as being most important for life satisfaction (Anderson, 2004). Common to the safe and successful completion of all of these tasks is the requirement of postural control. Without postural control, movement is limited and independence compromised.

The term postural control is often used interchangeably with the terms balance or balance control. Indeed, these are similar and inter-related constructs. Postural control refers to one's ability to maintain, achieve, or restore a state of balance at any given time (Pollock, Durward, Rowe, & Paul, 2000). From a biomechanical perspective, balance refers to the relationship between one's center of mass and one's base of support (Maki & McIlroy, 1997). When the vertical projection of one's center of mass moves outside of one's base of support, muscle activity is required to change the base of support or reposition the center of mass within the base of support. Without this corrective muscle activity, a fall would result. Achieving a state of balance, or postural control, is required when maintaining a posture (e.g., sitting or standing), moving voluntarily, or reacting to an external perturbation (e.g., trip, push) (Pollock et al., 2000).

For many individuals living with SCI/D, postural control is an ongoing challenge due to the sensorimotor deficits associated with their injury. Falling is common after SCI/D; 78% (95% confidence interval: 73%–83%) of ambulators fall each year, while 69% (95% confidence interval: 60%–76%) of wheelchair users fall (Khan et al., 2019). Falls have a significant

Diagnosis and Treatment of Spinal Cord Injury. https://doi.org/10.1016/B978-0-12-822498-4.00016-6

detrimental impact on those living with SCI/D (Musselman, Arnold, Pujol, Lynd, & Oosman, 2018; Singh et al., 2020). Up to 62% of ambulators and 38% of wheelchair users have reported a physical injury from a fall, with most injuries being minor in nature (i.e., cuts, bruises) (Khan et al., 2019). The most common serious injuries include fractures and head trauma with a loss of consciousness (Khan et al., 2019). More than 50% of chronic wheelchair users with SCI/D experience osteoporosis (Jensen et al., 2013); hence, these individuals are at high risk of sustaining a fall-related fracture (Jannings, 2017).

In addition to physical injury, those who fall or who have a high fall risk may develop a fear of falling, defined as an enduring concern about falling that causes one to avoid activities despite being physically able to perform them (Brouwer, Musselman, & Culham, 2004). About 47% to 63% of people living with SCI/D report a fear of falling (Butler Forslund, Roaldsen, Hultling, Wahman, & Franzén, 2016; Chan et al., 2020). This fear often leads to a "post-fall syndrome" characterized by dependence, loss of autonomy, depression, anxiety, reduced mobility and restricted participation in daily activities (World Health Organization, 2007). Individuals living with SCI/D describe the harmful psychosocial impact of falls, including feelings of vulnerability and embarrassment, lost work productivity, interference with parenting, and a restriction of meaningful recreational activities (Singh et al., 2020). The constant threat of falling, and fear of the potential consequences of a fall, can have a significant impact on quality of life (Singh et al., 2020).

Chapter objectives

Postural control is inherent to our ability to move and function safely, but is commonly impaired following SCI/D. Hence, improving postural control is a target of rehabilitation assessment and intervention across the continuum of care (i.e., from acute care to community rehabilitation). Regardless of neurological level of injury, severity of the SCI/D (i.e., as indicated by the American Spinal Injury Association Impairment Scale (AIS)), time since injury or mobility status, an evaluation of postural control is warranted for all individuals living with SCI/D. Yet, clinicians and researchers lack guidance on how to approach the assessment of postural control after SCI/D, especially given the heterogeneity in clinical presentation of this population. The primary aim of this narrative review is to outline an individualized and comprehensive approach to the assessment of postural control after SCI/D. The secondary aims are to: (1) describe common impairments in postural control following SCI/D, and (2) describe the current state of postural control assessment for individuals with SCI/D.

Comprehensive assessment of postural control

More than 30 measures of postural control have been used in research studies with the SCI/D population (Arora, Oates, Lynd, & Musselman, 2020). Hence, the challenge of postural control assessment post-SCI/D is not the availability of measures, but rather deciding which measure(s) to use. In their systematic review, Arora, Oates, et al. (2020) considered the psychometric properties, clinical utility and comprehensiveness of each measure. A measure's comprehensiveness is a relatively new concept that reflects the complexity of postural control. Postural control requires the complex interaction of numerous musculoskeletal and neurophysiological mechanisms, which are effectively outlined in the Systems Framework for Postural Control (Horak, 2006; Sibley, Beauchamp, Van Ooteghem, Straus, & Jaglal, 2015). In the original framework, Horak (2006) described six systems that contribute to postural control and suggested that appropriate evaluation of each system would enable identification of an individual's specific impairments and compensations, promoting individualized treatments. In 2015, Sibley and colleagues led a revision of the Framework, resulting in the identification of nine contributing systems (see Table 1); functional stability limits, underlying motor systems, static stability, verticality, reactive postural control, anticipatory postural control, dynamic stability, sensory integration, and cognitive influences. This revised Systems Framework for Postural Control provides a basis for a comprehensive assessment of postural control for individuals with SCI/D.

Following SCI/D, impairments in postural control are expected. The spinal cord contains numerous descending motor spinal pathways that are involved in the regulation of postural control through activation of postural synergies (Beloozerova, Sirota, Orlovsky, & Deliagina, 2005; Zelenin, Beloozerova, Sirota, Orlovsky, & Deliagina, 2010). There are also a number of ascending pathways, which carry somatosensory information to the brain and allow the adaptation of postural control to the environment (Chiba, Takakusaki, Ota, Yozu, & Haga, 2016). The extent of the impairments in postural control due to the SCI/D depends on the neurological level and severity of injury. The resulting impairments are more pronounced in a sub-set of the postural control systems (see Table 1 and Fig. 1). All individuals with SCI/D are likely to experience impairments in functional stability limits, underlying motor systems (e.g., muscle strength and coordination), static stability and sensory integration. Research involving individuals with motor incomplete SCI/D (i.e., AIS C and D) demonstrated deficits in reactive postural control (Arora, Musselman, et al., 2020; Chan et al., 2020) and cognitive influences (Lemay et al., 2020; Tse et al., 2017). For dynamic stability, the overall findings are variable. Individuals with

TABLE 1 Ten components of a comprehensive assessment of postural control.

(1) **Functional Stability Limits** (Horak, 2006; Sibley et al., 2015)	
Definition:	• The ability to move the COM within the base of support (base of support includes mobility aid, wheelchair).
Example Activities:	• Reaching in sitting or standing. • Reaching for the armrest when transferring. • Leaning for pressure relief in sitting.
Impact of SCI/D:	• Impaired Decreased control over COM resulting in longer path to stability limit and smaller functional boundaries in sitting (AIS A, C, D) (Shin & Sosnoff, 2013) and standing (AIS C, D) (Houston, Unger, Lee, Masani, & Musselman, 2020; Lemay et al., 2014).
(2) **Underlying Motor Systems** (Horak, 2006; Sibley et al., 2015)	
Definition:	• Muscular and neuromuscular properties contributing to strength and coordination.
Example Activities:	• Leg and trunk strength and/or sequence of muscle activation to transfer from sitting to standing, climb stairs, take a step, etc. • Trunk strength and/or sequence of muscle activation to lean in sitting.
Impact of SCI/D:	• Impaired Varying degrees of decreased strength below level of SCI/D. Reduced trunk-leg movement coordination in standing (AIS C, D) (Noamani, Lemay, Musselman, & Rouhani, 2020). Role of trunk strength on postural control in sitting after SCI/D is unclear (AIS A) (Chen et al., 2003).
(3) **Static Stability** (Horak, 2006; Sibley et al., 2015)	
Definition:	• The ability to control the COM within a static base of support during sitting and standing.
Example Activities:	• Independent sitting without trunk or upper limb support. • Independent standing without upper limb support.
Impact of SCI/D:	• Impaired Increased postural sway in sitting (AIS A, B, C) (Milosevic, Gagnon, Gourdou, & Nakazawa, 2017) and standing with greater deficits without vision (AIS D) (Lemay et al., 2013).
(4) **Verticality** (Horak, 2006; Sibley et al., 2015)	
Definition:	• The ability to align the body with respect to gravity.
Example Activities:	• Standing, sitting or walking on an incline or decline.
Impact of SCI/D:	• Minimal Increased variability in perception of vertical; however, reliance on visual and vestibular inputs compensates for decreased somatosensation (AIS A) (Joassin, Bonniaud, Barra, Marquer, & Perennou, 2010).
(5) **Reactive Postural Control** (Horak, 2006; Sibley et al., 2015)	
Definition:	• The ability to return the COM within the base of support after an external perturbation using corrective motor strategies (e.g., ankle and hip strategies, reactive stepping).
Example Activities:	• Taking step(s) to recover from a slip on ice. • Flexing/extending at the hips when balance has been lost posteriorly/anteriorly on a fixed base of support (e.g., balance beam, crowded subway platform).
Impact of SCI/D:	• Impaired Decreased ability to execute single step responses during a forward fall in standing (AIS C, D) (Chan et al., 2020). Able to maintain state of balance in standing during unexpected surface perturbations (AIS D) (Thigpen et al., 2009). Decreased ability to increase margin of stability in response to a slip while walking (AIS D) (Arora et al., 2020).
(6) **Anticipatory Postural Control** (Horak, 2006; Sibley et al., 2015)	
Definition:	• The ability to shift the COM appropriately prior to discrete movements.
Example Activities:	• When turning the head to look behind the body, shifting body weight toward the direction of the turn. • Walking with decreased speed, shorter step length, wider step width and a flatter foot-floor angle when on a slippery surface.

Continued

TABLE 1 Ten components of a comprehensive assessment of postural control—cont'd

Impact of SCI/D:	• Likely impaired with more severe SCI/D • Minimal for less severe SCI/D Able to modulate timing and amplitude of muscle activity in lower limb muscles in response to expected surface perturbations (AIS D) (Thigpen et al., 2009). Able to use anticipatory strategies in a similar manner to individuals without SCI/D when walking on known slippery surface (AIS D) (Bone et al., 2021).
(7) **Dynamic Stability** (Horak, 2006; Sibley et al., 2015)	
Definition:	• The ability to control the COM while the base of support is changing (e.g., during walking).
Example Activities:	• Walking, transferring.
Impact of SCI/D:	• Likely impaired with more severe SCI/D • Variable findings for less severe SCI/D Increased inter-stride variability of gait parameters (e.g., cadence, gait cycle time) (AIS D) (Lemay et al., 2020). Increased foot placement variability during treadmill walking (AIS D) (Day, Kautz, Wu, Suter, & Behrman, 2011). Stabilizing and destabilizing forces during single support phase of gait suggest increased stability (AIS D) (Lemay, Duclos, Nadeau, Gagnon, & Desrosiers, 2014). Increased stability during walking (i.e., decreased speed, shorter steps, greater percentage of time in double support) (Arora et al., 2019).
(8) **Sensory Integration** (Horak, 2006; Sibley et al., 2015)	
Definition:	• The ability to combine sensory input from multiple sources and re-weight when input is altered.
Example Activities:	• Transitioning between different surfaces when walking (e.g., pavement to sand). • Transitioning between environments with varying degrees of light (e.g., bright theatre lobby to dark theatre).
Impact of SCI/D:	• Impaired Increased reliance on visual input (i.e., decreased ability to re-weight sensory input) during standing (AIS D) (Lemay et al., 2013; Noamani, Lemay, Musselman, & Rouhani, 2021) and walking (AIS D) (Lemay et al., 2020) under different sensory conditions.
(9) **Cognitive Influences** (Horak, 2006; Sibley et al., 2015)	
Definition:	• The ability to maintain postural control while responding to commands during a task or attending to additional tasks (i.e., dual tasking).
Example Activities:	• Responding to an instruction to increase speed while walking. • Attending to a cognitive load (e.g., conversing, mental math) while sitting, standing or walking.
Impact of SCI/D:	• Impaired Cognitive dual-task decreased standing time (AIS C, D) (Tse, Carpenter, Liu-Ambrose, Chisholm, & Lam, 2017) and increased inter-stride variability of cadence when walking (AIS D) (Lemay et al., 2020).
(10) **Balance Confidence** (Hatch, Gill-Body, & Portney, 2003)	
Definition:	• The level of perceived confidence in the ability to maintain a state of balance while performing daily activities.
Example Activities:	• Having confidence to complete daily activities (e.g., get onto an escalator, reach for something on tiptoes, and walk on an uneven surface) without losing balance.
Impact of SCI/D:	• Impaired Decreased balance confidence during standing and walking activities (AIS C, D) (Shah, Oates, Arora, Lanovaz, & Musselman, 2017). Greater balance confidence associated with decreased velocity of COP in standing (AIS C, D) (Shah et al., 2017). Decreased falls self-efficacy associated with increased postural sway in standing with bilateral KAFO (AIS A) (John, Cherian, & Babu, 2010).

An original table providing the definition of each component of postural control along with example activities. A description of the observed impact of spinal cord injury or disease (SCI/D) on each component is summarized. *COM*, center of mass; *AIS*, American Spinal Injury Association Impairment Scale; *COP*, center of pressure; *KAFO*, knee ankle foot orthoses.

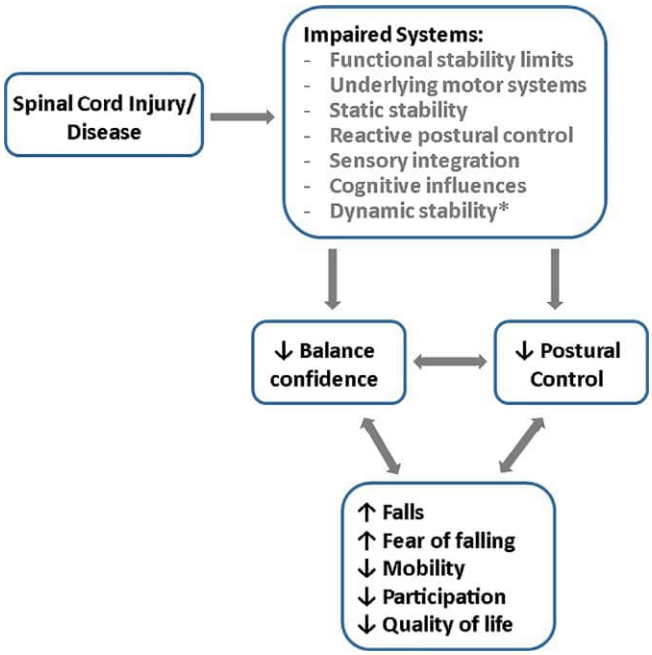

FIG. 1 Effect of spinal cord injury/disease on the systems of postural control. An original figure summarizing the systems of postural control that are negatively affected by spinal cord injury or disease (*conflicting research findings concerning dynamic stability). These impaired systems result in reduced postural control and balance confidence, with these two constructs influencing one another. Reduced postural control and balance confidence can negatively impact the occurrence and fear of falls, mobility, participation and quality of life, resulting in a cycle of decline whereby falls and decreased mobility/participation result in further decreases in postural control and confidence.

AIS D SCI/D show variability in gait parameters, suggesting compromised dynamic stability (Day et al., 2011; Lemay et al., 2020); however, they also show markers of greater stability during walking than age- and sex-matched able-bodied adults (Arora et al., 2019; Lemay, Duclos, et al., 2014). Arora et al. (2019) proposed that increased stability when walking may be a compensatory strategy to avoid losing balance and having to rely on an impaired reactive postural control system to prevent a fall. There do not appear to be impairments in anticipatory postural control for those individuals with the least severe SCI/D (i.e., AIS D) (Bone et al., 2021; Thigpen et al., 2009), but deficits may be evident in those with greater sensorimotor deficits. Lastly, SCI/D does not affect verticality (Joassin et al., 2010), although deficits may occur in individuals with a relevant co-morbidity, such as a vestibular disorder or brain injury.

Not only do the above-mentioned physiological factors influence postural control, but so do psychological factors, such as balance confidence (Carpenter, Adkin, Brawley, & Frank, 2006). Balance confidence or self-efficacy refers to an individual's perceived self-confidence in maintaining a state of balance during relatively non-hazardous activities (Hatch et al., 2003). The Systems Framework for Postural Control does not account for the effect of this psychological construct on postural control. However, due to the associations between balance confidence and postural control after SCI/D (John et al., 2010; Shah et al., 2017) (see Table 1 and Fig. 1), a measure of balance confidence should be included as the tenth component of a comprehensive assessment of postural control (see Fig. 2). This inclusion allows the clinician or researcher to evaluate the alignment between an individual's perceived balance confidence and physical abilities. For example,

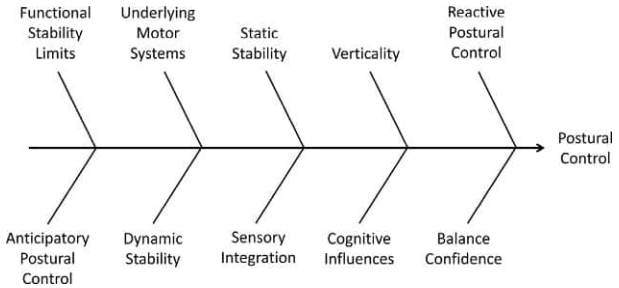

FIG. 2 Fishbone diagram of postural control after spinal cord injury/disease. An original figure highlighting ten components that impact postural control.

perceived balance confidence may be high while the physical ability to maintain a state of balance is low. These findings may suggest an individual lacks insight into his/her postural control deficits, resulting in a high fall risk due to an increased likelihood of risk-taking behaviors. Conversely, someone with low balance confidence, but capable of maintaining a state of balance during daily activities, may needlessly restrict their mobility and participation due to an exaggerated concern about falling. Hence, balance confidence adds a unique dimension to the comprehensive assessment of postural control.

Current state of postural control assessment in clinical settings

Survey studies involving more than 400 Canadian physical therapists have shed light on the postural control assessment practices for adult populations (Oates et al., 2017; Sibley, Straus, Inness, Salbach, & Jaglal, 2011). While the researchers reported variation in how postural control was assessed clinically, they noted that several postural control systems were regularly evaluated (i.e., by >80% of respondents): static stability, dynamic stability and underlying motor systems (Sibley et al., 2011). In contrast, reactive postural control was evaluated by only 41% of respondents (Sibley et al., 2011). The most commonly used measures of postural control included movement observation, the Berg Balance Scale and the single-leg stance test (Oates et al., 2017; Sibley et al., 2011). In another survey by Sibley, Straus, Inness, Salbach, and Jaglal (2013), 94% of physical therapists agreed that quantifying impairments in postural control was critical for patient care; however, only 43% of respondents agreed that existing measures of postural control were adequate for clinical practice. Moreover, even fewer (21%) indicated that these measures evaluated postural control in a comprehensive way (Sibley et al., 2013), highlighting a key gap in current approaches to the assessment of postural control.

Several organizations have produced clinical recommendations regarding the assessment of postural control. The American Physical Therapy Association and the Academy of Neurological Physical Therapy supported the development of a core set of outcome measures for adults with neurological conditions (Moore et al., 2018). The recommended measures of postural control include the Berg Balance Scale for static and dynamic sitting and standing, the Functional Gait Assessment for dynamic balance, and the Activities-specific Balance Confidence (ABC) Scale for balance confidence. More specific to the SCI/D population, the Canadian Standing and Walking Module Group produced the Standing and Walking Assessment Tool (SWAT) (Musselman et al., 2019). The SWAT is a SCI/D-specific, staged approach to the standardized assessment of standing and walking ability post-SCI/D. Within the SWAT, the Berg Balance Scale is recommended for the majority of individuals with SCI/D (i.e., those who have at minimum the ability to stand with assistance) while the ABC Scale is recommended for those who ambulate, whether therapeutically with assistance or independently in the community (Musselman, Lemay, et al., 2019). In sum, these two practice guidelines are aligned and highlight appropriate measures of postural control for the SCI/D population. However, as outlined below, the Berg Balance Scale and ABC Scale on their own do not fulfill the requirement of a comprehensive and individualized approach to the assessment of postural control after SCI/D.

Arora, Oates, et al. (2020) concluded their systematic review with recommendations for the clinical assessment of postural control after SCI/D. They concluded that of the >30 measures reviewed "no single measure had high clinical utility, strong psychometric properties and comprehensiveness" (Arora, Oates, et al., 2020). The Berg Balance Scale and Functional Reach Test were highlighted for their well-established psychometric properties in the SCI/D population, while the mini-Balance Evaluation Systems Test (mini-BESTest) was identified as the most comprehensive measure that has been used with individuals with SCI/D. The mini-BESTest was developed from the original Systems Framework of Postural Control, and is one of the only clinical measures that evaluates reactive postural control (Arora, Oates, et al., 2020; Horak, Wrisley, & Frank, 2009). Since Arora, Oates, et al. (2020) completed the database searching for their review, the mini-BESTest has been shown to be a valid and reliable measure of postural control for individuals with motor incomplete SCI/D (Chan et al., 2019; Jørgensen, Opheim, Halvarsson, Franzén, & Roaldsen, 2017). Given the comprehensiveness, strong psychometric properties and high clinical utility of the mini-BESTest, its use among the SCI/D population is expected to increase.

Instrumented assessments of postural control

In addition to the above-mentioned clinical measures, there are instrumented assessments of postural control involving force plates and inertial measurement units (IMU) that have primarily been used in research settings. These instruments can be adapted to facilitate assessment of the components of postural control, with the exception of balance confidence. In their review, Arora, Oates, et al. (2020) highlighted the use of instrumented assessments of postural control among the SCI/D population. Center of pressure-based measures of postural sway, quantified with force plates, were most commonly used (Arora, Oates, et al., 2020). Force plates consist of a rigid surface instrumented with multiple force transducers allowing the measurement of forces in three dimensions. Force plate-based measures of postural sway are considered the gold standard measure of postural control in standing (Ghislieri, Gastaldi, Pastorelli, Tadano, & Agostini, 2019). They are a valid and

reliable tool for the evaluation of standing postural control among individuals with incomplete SCI/D (Tamburella, Scivoletto, Iosa, & Molinari, 2014). More specifically, force plates have been used to quantify the performance of functional stability limits (Houston et al., 2020; Lemay, Gagnon, et al., 2014), underlying motor systems (Lee et al., 2021), static stability (Lemay et al., 2013), anticipatory postural control (Arora et al., 2019), dynamic stability (Arora et al., 2019), sensory integration (Lemay et al., 2013) and cognitive influences (Tse et al., 2017). More recently, force plates have been used to assist with the identification of spatiotemporal deficits in reactive postural control (Chan et al., 2020), with some metrics showing adequate validity and reliability (Unger et al., 2020).

IMU are being increasingly used to quantify postural control during sitting (Perez-SanPablo, Quinzanos-Fresnedo, Lopez-Romero, & Quinones-Uriostegui, 2018), standing (Noamani et al., 2020, 2021) and walking (Lemay et al., 2020). IMU typically include accelerometers to measure linear acceleration and gyroscopes to measure angular velocity, and may include magnetometers to measure the amplitude and direction of magnetic fields (Ghislieri et al., 2019). Information characterizing postural control in static standing can be collected with a single IMU (Noamani et al., 2021); however, multiple sensors are needed to extract information about more complex and dynamic postural tasks (Lemay et al., 2020; Noamani et al., 2020). Their reliability and/or validity for use during sitting, standing and walking with individuals with SCI/D have been established (Lemay et al., 2020; Noamani et al., 2020; Perez-SanPablo et al., 2018). IMU can be used in a variety of contexts and for a variety of tasks, and therefore address a number of the components of postural control. For example, among the SCI/D population, IMU have been used to quantify underlying motor systems (Noamani et al., 2020), static stability (Noamani et al., 2020), dynamic stability (Lemay et al., 2020), sensory integration (Lemay et al., 2020; Noamani et al., 2021) and cognitive influences (Lemay et al., 2020).

Although IMU and force plates can facilitate a comprehensive assessment of postural control, these tools tend to have low clinical utility due to their high cost, high level of skill required to administer and interpret the measure, and in the case of force plates, their low portability (Arora, Oates, et al., 2020). As low-cost alternatives to these instrumented tools are developed, their use in clinical settings is likely to increase.

Individualized and comprehensive assessment of postural control after SCI/D

When an individual with SCI/D begins a rehabilitation program, whether during the acute, sub-acute or chronic phase of recovery, a comprehensive and individualized approach to the assessment of postural control is warranted. Evaluation of the ten components of postural control (see Table 1 and Fig. 2) will ensure the initial assessment is comprehensive. A comprehensive approach will allow the identification of an individual's unique impairments in postural control, thereby identifying the components that should be addressed in therapy and monitored throughout the rehabilitation process at subsequent assessments.

In addition to being comprehensive, the assessment of postural control should be individualized to a person's level of mobility and function. The majority of clinical measures are not applicable to all levels of SCI/D severity. For example, the Berg Balance Scale has a ceiling effect for individuals with AIS D SCI/D (Chan et al., 2017; Jørgensen et al., 2017; Lemay & Nadeau, 2010). To select the measures of postural control most appropriate for an individual, mobility status should be considered. The above-mentioned SWAT is a standardized approach to the staging of mobility status after SCI/D that has been used at Canadian rehabilitation hospitals since 2015 (Musselman, Lemay, et al., 2019). The SWAT stages span all possible levels of mobility and postural control, from Non-independent Sitting Capacity (Stage 0) to Full Walking Capacity (Stage 4) (see Fig. 2). Stage 1 (Standing Capacity), Stage 2 (Therapeutic Walking Capacity (indoors)) and Stage 3 (Functional Walking (outdoors)) are each further divided into three stages, resulting in 12 stages that span the continuum of standing and walking ability. Definitions for each stage are provided to assist physical therapists with the staging process (see Table 2). The SWAT links these stages of mobility with well-established, clinical measures of gait (i.e., 10-m walk test, 6-min walk test) and balance (i.e., Berg Balance Scale, ABC Scale), aiding physical therapists in their selection of appropriate measures to use with an individual (Musselman, Lemay, et al., 2019). The validity and responsiveness of the SWAT stages have been established (Musselman et al., 2019; Musselman, Lemay, et al., 2019).

The SWAT can be used to determine which clinical measures to include in an individual's assessment of postural control. The recommended measures change as the SWAT stages progress from minimal sitting capacity to full community ambulation (see Fig. 3). The selection of clinical measures was guided by the above-mentioned, pre-existing recommendations of the Canadian SCI Standing and Walking Module Group, the American Physical Therapy Association and the Academy of Neurological Physical Therapy, as well as by the review completed by Arora, Oates, et al. (2020). The selected measures have high clinical utility, strong psychometric properties in the SCI/D population and are freely available. The following sections include descriptions of each measure along with an explanation of how the measure fits into a comprehensive assessment of postural control. The sections are organized according to three groupings of SWAT stages (Bayley

TABLE 2 Standing and walking assessment tool stages of walking recovery.

SWAT stage	Classification		Definition
0.0	Non-independent sitting capacity		Individual is unable to sit independently of a seating system on a firm surface with hips and knees at 90 degrees and feet on the floor for 60 s without using arms to stabilize.
0.5	Independent sitting capacity		Individual is able to sit independently of a seating system on a solid surface with hips and knees at 90 degrees and feet on the floor for 60 s without using arms to stabilize.
1	Standing capacity		Individual cannot ambulate but may be able to stand with assistance
	1A	Trace L/E movement	Unable to stand without total assistance of gait aid and/or orthoses and/or therapist(s). No voluntary L/E functional movement. (L/E MMT ≤ grade 1 in tibialis anterior, soleus, quads, and gluteus.)
	1B	Voluntary Non-Functional L/E movement	Unable to stand independently/needs partial assistance of gait aid and/or orthoses (except bilateral KAFO) and/or therapist(s) to stand. The use of bilateral KAFO is not allowed. Voluntary L/E Movement (L/E MMT of grade 1 +/2- to grade 3- in anti-gravity muscles).
	1C	Voluntary Functional L/E movement	Able to stand independently with minimal assistance of gait aid for limited amount of time (<30 s). Orthoses are allowed except for bilateral KAFO. Voluntary L/E Movement. (L/E MMT of grade 3 or higher in most anti-gravity muscles except grade 1 tibialis anterior with an orthosis would fit this group.)
2	Therapeutic walking capacity (indoors)		Individual is starting to ambulate with therapist assistance and gait aids/orthoses and progresses toward minimal assistance.
	2A	Maximal assistance	Ability to stand and initiate reciprocal steps through voluntary L/E movement but requires maximal physical assistance (>50% of total effort) of at least one person and may include use of assistive devices and/or orthoses with the exception of bilateral KAFO.
	2B	Moderate assistance	Ability to stand and initiate reciprocal steps through voluntary L/E movement but requires moderate physical assistance (25%–50% of total effort) of one person and may include use of assistive devices and/or orthoses with the exception of the bilateral KAFO.
	2C	Minimal assistance	Ability to stand and initiate reciprocal steps through voluntary L/E movement but requires minimal physical assistance (<25% of total effort) of one person and may include use of assistive devices and/or orthoses with the exception of the bilateral KAFO.
3	Functional walking (outdoors)		Individual is starting to ambulate without therapist assistance, but still requires gait aids/orthoses. Individual progresses to ambulating in the community.
	3A	Supervised household ambulator	Ability to ambulate daily using reciprocal steps over ground for short distances (10–100 m) with supervision. Individual may use assistive devices and/or orthoses with the exception of bilateral KAFO.
	3B	Independent household ambulator	Ability to ambulate daily using reciprocal steps over ground for short distances (10–100 m) independently. Individual may use assistive devices and/or orthoses with the exception of the bilateral KAFO.
	3C	Community ambulator	Ability to ambulate daily using reciprocal steps over ground for long distances (>100 m) independently. Individual may use assistive devices and/or orthoses with the exception of the bilateral KAFO.
4	Full walking capacity		Individual ambulates independently without therapist assistance or gait aids/orthoses. Independent ambulator—ability to ambulate full time daily at home and in the community without assistive devices, orthoses, or physical assistance.

Classification and definition for each stage of the Standing and Walking Assessment Tool (SWAT). *SCI*, spinal cord injury; *L/E*, lower extremity; *MMT*, manual muscle testing; *KAFO*, knee ankle foot orthoses.

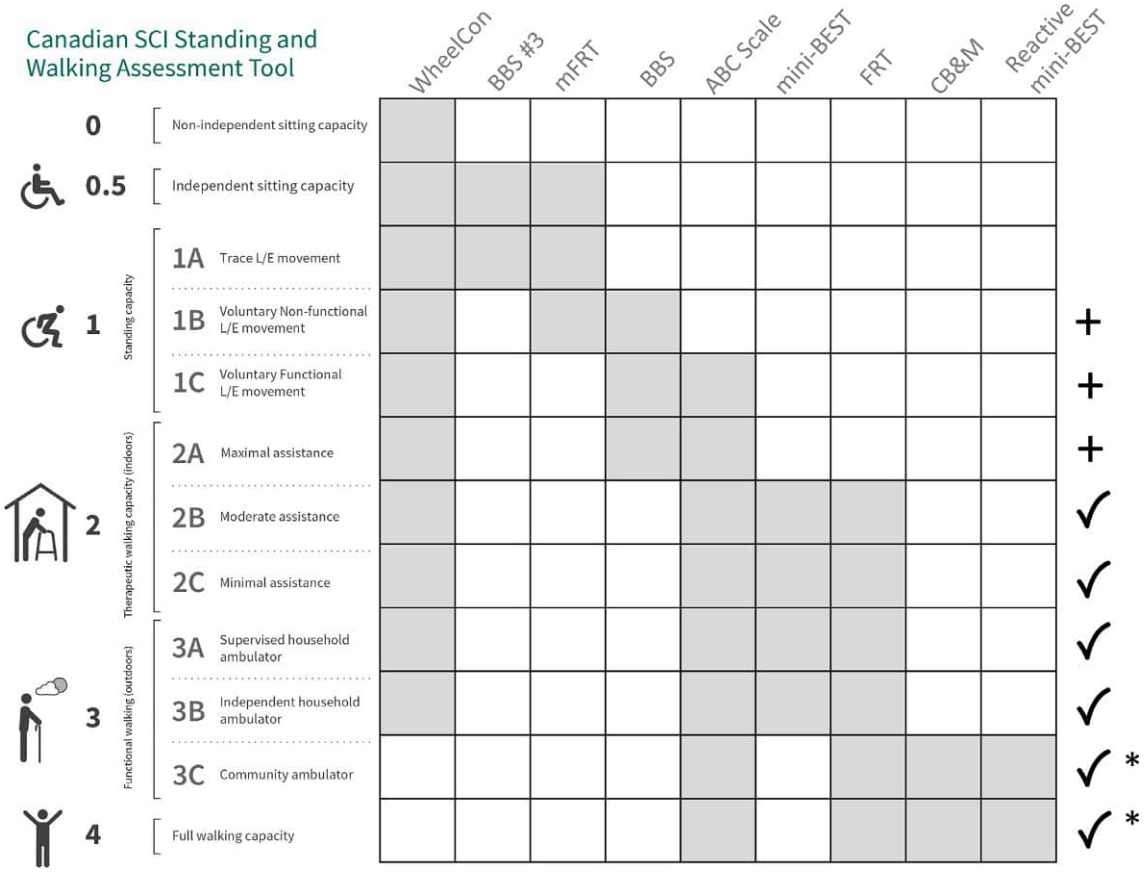

FIG. 3 Individualized and comprehensive approach to postural control assessment. The stages of the Standing and Walking Assessment Tool (left, reproduced with permission from the Canadian SCI Standing and Walking Module Group) are used to identify which clinical measures of postural control are appropriate for each stage. +Additional non-standardized measures of reactive postural control, cognitive influences and verticality in sitting could be added to increase comprehensiveness. √ All components of postural control assessed by recommended measures. √*All components of postural control, with the exception of verticality, assessed by recommended measures. *BBS #3*, third item on the Berg Balance Scale (BBS); *Reactive mini-BEST*, Reactive sub-scale of the mini-Balance Evaluation Systems Test (mini-BESTest); *SCI*, spinal cord injury; *L/E*, lower extremity; *WheelCon*, Wheelchair Use Confidence Scale v.3; *mFRT*, modified Functional Reach Test; *ABC Scale*, Activities-specific Balance Confidence Scale; *FRT*, Functional Reach Test; *CB&M*, Community Balance and Mobility Scale.

et al., 2019): (1) wheelchair users with varying degrees of independence in sitting and standing (i.e., Stages 0 through 2A); (2) part-time ambulators who also use a wheelchair for mobility (i.e., Stages 2B through 3B); and (3) full-time community ambulators (i.e., Stages 3C and 4).

Wheelchair users: Assessment of postural control

For individuals with SCI/D who are at a Stage 0 through 2A on the SWAT, the assessment of postural control is focused on sitting and standing activities, as appropriate for the individual's level of function (see Table 2). The clinical measures recommended for these SWAT stages address some, but not all, of the components of postural control (see Fig. 3 and Table 3).

Stage 0

A meaningful postural control assessment for individuals lacking independent sitting capacity is limited to an evaluation of balance confidence. To gauge balance confidence in a wheelchair user, the Wheelchair Use Confidence Scale v.3 (WheelCon) can be used, with separate versions available for manual and power wheelchair users (Rushton, Miller, Kirby, Eng, & Yip, 2011). The questionnaire measures one's confidence in using a wheelchair according to six wheelchair-related topics: wheelchair activities, negotiating the physical environment, knowledge and problem solving,

Reactive mini-BESTest					✓					

Clinical measures recommended for a comprehensive and individualized approach to postural control assessment after spinal cord injury or disease are listed (left). √The component of postural control is assessed by the clinical measure (Arora, Oates, et al., 2020; Sibley et al., 2015). *BBS #3*, third item on the Berg Balance Scale (BBS); *Reactive mini-BEST*, Reactive sub-scale of the mini-Balance Evaluation Systems Test (mini-BESTest); *WheelCon*, Wheelchair Use Confidence Scale v.3; *mFRT*, modified Functional Reach Test; *ABC Scale*, Activities-specific Balance Confidence Scale; *FRT*, Functional Reach Test; *CB&M*, Community Balance and Mobility Scale.

advocacy, managing emotions and managing social situations (Rushton et al., 2011). The WheelCon was shown to have excellent reliability, validity and responsiveness in a group of wheelchair users, 60% of whom had SCI/D (Rushton, Miller, Kirby, & Eng, 2013).

Stages 0.5 and 1A

For those individuals with no standing capacity, but independent sitting capacity, the assessment of postural control is focused on a few appropriate components: (1) balance confidence related to wheelchair use, as measured with the WheelCon; (2) static stability in sitting, as measured with item three on the Berg Balance Scale, "Sitting with Back Unsupported but Feet Supported on Floor or on Stool" (Berg, Wood-Dauphinee, Williams, & Gayton, 1989); and, (3) functional stability limits, underlying motor systems and anticipatory postural control in sitting, as measured by the modified Functional Reach Test. The modified Functional Reach Test measures the maximum distance one can reach in a seated position. It has validity and reliability in both the motor complete (Lynch, Leahy, & Barker, 1998) and motor incomplete SCI/D (Field-Fote & Ray, 2010) populations.

Stages 1B, 1C, and 2A

For individuals with minimal ability to step, a greater number of the components of postural control can be evaluated through inclusion of the entire Berg Balance Scale. The Berg Balance Scale evaluates balance control during 14 sitting and standing tasks, such as chair-to-chair transfers and reaching forward in standing (Berg et al., 1989). It is a valid and reliable measure of balance for the SCI/D population (Wirz, Muller, & Bastiaenen, 2010). Although the Berg Balance Scale increases the comprehensiveness of the assessment for wheelchair users, several components of postural control are missing from this clinical measure: reactive postural control, cognitive influences and verticality (Arora, Oates, et al., 2020). To address these gaps in assessment, non-standardized evaluations of reactive postural control and dual tasking in sitting could be added. If an individual presents with a co-morbid condition known to affect verticality, then a non-standardized evaluation of this postural control system in sitting could be included.

To evaluate balance confidence, the WheelCon is recommended for individuals staged at 1B through 2A. However, for individuals who are beginning to stand (i.e., Stages 1C and 2A), the ABC Scale should also be included to gauge balance confidence during upright activities. The ABC Scale asks individuals to rate their confidence, from 0% to 100%, in their ability to maintain balance while performing 16 standing and walking tasks (Powell & Myers, 1995). The ABC Scale has validity and reliability among individuals with chronic incomplete SCI/D (Shah et al., 2017).

Part-time ambulators: Assessment of postural control

At Stages 2B through 3B, individuals with SCI/D can stand, but have varying degrees of ambulatory ability and are likely using a wheelchair to meet some of their mobility needs (see Table 2). At these SWAT stages, an assessment including all 10 components of postural control is achieved by combining two clinical scales (i.e., the mini-BESTest and the Functional Reach Test) and two questionnaires that query balance confidence (i.e., the WheelCon and the ABC Scale) (see Fig. 3 and Table 3).

For part-time ambulators, the mini-BESTest is the clinical measure of choice. The mini-BEST is the most comprehensive measure of postural control that has been used with the SCI/D population (Arora, Oates, et al., 2020). It is also known to have less of a ceiling effect than the Berg Balance Scale (Jørgensen et al., 2017). The mini-BESTest assesses four balance control systems: anticipatory, reactive postural control, sensory orientation and dynamic gait (Franchignoni, Horak, Godi, Nardone, & Giordano, 2010). The mini-BESTest and its sub-scales have validity and reliability among the chronic incomplete SCI/D population (Chan et al., 2019; Jørgensen et al., 2017). As the mini-BESTest evaluates all systems outlined in the modified Systems Framework for Postural Control with the exception of functional stability limits (Arora, Oates, et al., 2020), it is recommended that the Functional Reach Test is used as well for part-time ambulators. The Functional Reach Test is similar to the modified Functional Reach Test, except it is performed in standing.

Full-time ambulators: Assessment of postural control

A comprehensive assessment of postural control that is appropriate for the high level of function of Stages 3C and 4 (see Table 2) is possible by combining a questionnaire of balance confidence (i.e., the ABC Scale) with three clinical measures (see Fig. 3 and Table 3). First, to evaluate functional stability limits, the Functional Reach Test is recommended. Second, to

evaluate reactive postural control, the Reactive sub-scale of the mini-BEST may be used. Third, to evaluate the remaining components of postural control, with the exception of verticality, the Community Balance and Mobility Scale is recommended. The Community Balance and Mobility Scale is a 19-item scale that evaluates performance on challenging balance tasks requiring speed and accuracy; for example, tandem walking, hopping forward, and running with a controlled stop (Inness et al., 2011). The tasks are completed without any assistance or gait aid. It is valid and reliable measure among inpatients with primarily AIS D SCI/D (Chan et al., 2017). Lastly, if an evaluation of verticality is indicated based on an individual's medical history, item 9 on the mini-BESTest (i.e., "Incline—Eyes Closed") (Franchignoni et al., 2010) could be included in the assessment.

Summary

Postural control assessment is a valued part of the rehabilitation of individuals living with SCI/D. Yet current approaches in clinical practice are unstandardized and rarely target all ten components of postural control. New measures are not needed to address these gaps; currently available clinical measures and questionnaires can be combined to create a comprehensive assessment of postural control. Instrumented tools, such as force plates and IMU, can be applied in a variety of contexts and tasks, contributing to a comprehensive assessment. The stages of the SWAT can be used to individualize the assessment to the individual's mobility status, providing clinicians and researchers with a standardized approach to the selection of clinical measures.

Applications to other areas of neuroscience

An assessment of postural control is a critical part of the rehabilitation for individuals with spinal cord injury or disease, as well as individuals living with other neurological conditions, such as stroke, Multiple Sclerosis, Parkinson's disease, and cerebral palsy. Despite differences in the nature and location of neurological damage across conditions, the principles of comprehensiveness and individualization apply to the postural control assessment for all. Each neurological condition will have a unique clinical presentation that can be characterized through standardized assessment of all components of postural control.

Similarly, the measures recommended for the assessment of postural control (see Fig. 3) are not specific to spinal cord injury or disease; many of these measures were developed and validated for other clinical populations. Only the stages of the Standing and Walking Assessment Tool are specific to spinal cord injury; however, these stages were developed from classification systems used with other neurological populations, such as the Functional Ambulation Categories. Moreover, the broad categories of mobility status presented here (i.e., wheelchair users, part-time ambulators, full-time ambulators) have applicability to other neurological conditions.

Mini-dictionary of terms

- **Anticipatory postural control**: The ability to shift one's center of mass appropriately prior to discrete movements.
- **Balance**: The term that describes the relationship between one's center of mass and one's base of support.
- **Balance confidence**: The level of perceived confidence in one's ability to maintain a state of balance while performing daily activities.
- **Cognitive influences**: The ability to maintain postural control while responding to commands during a task or attending to additional tasks (i.e., dual tasking).
- **Dynamic stability**: The ability to control one's center of mass while the base of support is changing (e.g., during walking).
- **Functional stability limits**: The ability to move one's center of mass within one's base of support.
- **Postural control**: One's ability to maintain, achieve or restore a state of balance when maintaining a posture, moving voluntarily, or reacting to an external perturbation.
- **Reactive postural control**: The ability to return one's center of mass within one's base of support after an external perturbation using corrective motor strategies (e.g., ankle and hip strategies, reactive stepping).
- **Sensory integration**: The ability to combine sensory input from multiple sources and re-weight when input is altered.
- **Static stability**: The ability to control one's center of mass within a static base of support during sitting and standing.
- **Underlying motor systems**: The muscular and neuromuscular properties that contribute to strength and coordination.
- **Verticality**: The ability to align one's body with respect to gravity.

Key facts of postural control

- Postural control is the ability to maintain, achieve or restore a state of balance when maintaining a posture (e.g., sitting, standing), moving (e.g., walking) or reacting to a perturbation (e.g., slip, trip), thereby preventing a fall.
- Physiological factors, such as muscle strength and coordination, and psychological factors, such as balance confidence, influence postural control.
- Impairments in postural control are experienced by most individuals living with spinal cord injury or disease, resulting in frequent falls.
- Clinicians view assessment of postural control as important for patient care.
- Movement observation, standardized clinical scales and instrumented measures, such as force plates and inertial measurement units, can be used to evaluate postural control.

Summary points

- Individuals with spinal cord injury or disease have impairments in postural control regardless of the neurological level or severity of injury.
- Following damage to the spinal cord, impairments in functional stability limits, underlying motor systems, static stability, sensory integration, reactive postural control, cognitive influences, dynamic stability and balance confidence are common.
- Clinicians and researchers lack a standardized and comprehensive approach to the assessment of postural control in individuals with spinal cord injury or disease.
- A comprehensive and individualized approach to the assessment of postural control is needed to tailor rehabilitation for each unique individual.
- A comprehensive assessment of postural control includes evaluation of ten components based on the Systems Framework of Postural Control combined with balance confidence.
- Instrumented measures, such as force plates and inertial measurement units, can contribute to comprehensive assessments of postural control.
- An individualized assessment is achieved by considering an individual's mobility status as outlined in the Stages of the Standing and Walking Assessment Tool.
- Based on an individual's Standing and Walking Assessment Tool Stage, clinical measures are combined to create a comprehensive assessment of postural control.

SCIM	spinal cord independence measure
SD	surgical decompression
SDSF	surgical decompression and segment fixation
STACSIS study	Surgical Timing in Acute Spinal Cord Injury study

Introduction

Historically, closed reduction with external immobilization was the milestone of treatment for acute SCI and only few cases were reserved for surgical management. However, in the last 2 decades, spine surgeons emphasized early surgical management of SCI (Hawryluk, Rowland, Kwon, & Fehlings, 2008; Rowland, Hawryluk, Kwon, & Fehlings, 2008; Wilson & Fehlings, 2011).

Preclinical studies suggested that persistent compression of spinal cord after primary injury is responsible for an additional secondary damage which might be avoided reducing tissue damage as soon as possible and improving outcomes (Dimar, Glassman, Raque, Zhang, & Shields, 1999; Fehlings & Perrin, 2006).

SDSF allows stabilization of vertebral column and decompression of spinal cord. Moreover, stabilization prevents any further trauma on spinal cord and allows early rehabilitation (Wilson et al., 2017).

Since vascular mechanisms of secondary injury after SCI were already discovered in the past, the practice of ESD has now biological support (Ahuja et al., 2017; Tator & Fehlings, 1991).

Removing spinal cord compression and restoring blood supply should reduce the biochemical process induced by ischemia due to local compression (Dolan, Tator, & Endrenyi, 1980; Guha, Tator, Endrenyi, & Piper, 1987; Rivlin & Tator, 1978).

Despite the increasing literature, there are still some unanswered questions about the optimal methods for ESD. We still don't know if all patients are going to benefit from ESD or if there are subgroups which are more likely to benefit than others

Diagnosis and Treatment of Spinal Cord Injury. https://doi.org/10.1016/B978-0-12-822498-4.00017-8

TABLE 1 SCI severity.

Classification of spinal cord injury (SCI) severity			
Normal neurological condition	**Incomplete SCI**	**Complete SCI**	**Clinical syndromes**
ASIA scale E	ASIA scale B, C or D	ASIA scale A	– Central Cord – Anterior Cord – Conus Medullaris – Cauda Equina – Brown-Sequard

ASIA scale scores are paired with normal neurological status or incomplete or complete SCI. In the fourth column all special clinical syndromes related to SCI are reported.

(Table 1). We still don't know the appropriate time for surgical intervention balancing key priorities of efficacy and clinical feasibility.

In this narrative review, we will highlight the situation of last 20 years literature about ESD in patients with acute SCI focusing to which subgroups of SCI will benefit from ESD and the time of surgical intervention.

Natural history of patients with acute cervical SCI

Approximately, one third of patients with cervical SCI has a complete injury. However, the incidence is double in patients with associated polytrauma (Stephan et al., 2015).

At 1 year from injury, 70% of patients with an initial ASIA (Table 2) score A injury will remain A, while about 30% of them will show some signs of improvement. Around 14% will improve to B, 9.5% to C, 6.5% to D, while none will improve to ASIA E (Wiberg & Hauge, 1988; Zariffa, Curt, & Steeves, 2012). On the other hand, patients with incomplete SCI have a much higher spontaneous recovery (Kirshblum, Millis, McKinley, & Tulsky, 2004).

Unfortunately, at 1 year after time of injury, patients with complete cervical SCI had a mean recovery ranging from 9.0 to 14 motor score points(Marino et al., 2011), calculating as motor score (ranging from 0 to 5 per muscle group), the strength for each muscle group below the lesion level (Maynard et al., 1997).

Neurological improvement will typically show within the first 3 months and then it will enter a steady state (Fawcett et al., 2007); even if in a little percentage of patients (about 9%) some little improvement can be showed even 5 years after injury (Ter Wengel, De Haan, Feller, Oner, & Vandertop, 2020).

Natural history of patients with thoracic or thoracolumbar SCI

A complete neurological injury is reported ranging from 16.2% to 73.0% of patients with acute thoracic SCI (Nijendijk, Post, & Van Asbeck, 2014) and it is more frequent in patients with polytrauma (Stephan et al., 2015) (Fig. 1).

TABLE 2 ASIA scale classification of neurological impairment.

ASIA scale	Description
A	COMPLETE. No motor or sensory function is preserved in the sacral segments S4-S5
B	INCOMPLETE. Sensory but not motor functions preserved under the level of lesion. It includes S4-S5
C	INCOMPLETE. Motor function is preserved below the neurological level and more than 50% of key muscles below the neurological level have a muscle grade less than 3
D	INCOMPLETE. Motor function is preserved below the neurological level and at least 50% of key muscles below the neurological level have a muscle grade greater than or equal to 3
E	NORMAL. Motor and sensory function are normal

ASIA scale scores are reported on the left and paired with the accurate description of signs and symptoms.

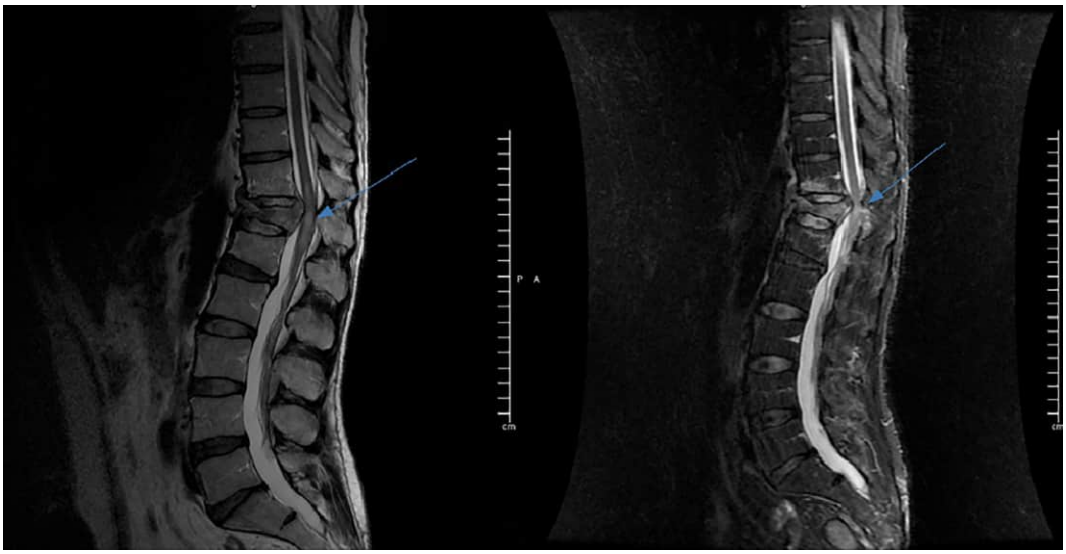

FIG. 1 Magnetic resonance imaging (MRI) about T12 fracture causing complete SCI. In this picture T2 *(left)* and STIR *(right)* MRI sequences of a SCI clinical case. The patient (46 years old, man) arrived after trauma occurred at home. On the left and on the right, marked by the *blue arrows*, hyperintensity can be seen (SCI lesion causing paraplegia).

At 1 year from injury, about 85% of patients with initial ASIA A will not improve, while about 15% of them will show 1 or more ASIA grade improvement. In patients with initial ASIA B, more than 80% of them will show some improvement (Fawcett et al., 2007; Zariffa et al., 2012).

Substantially, acute thoracic SCI will improve less than cervical or thoracolumbar SCI (Zariffa et al., 2011). In only 3.6% of patients with ASIA A grade at 1 year after injury, some minor neurological recovery can be recorded up till 5 years (Kirshblum et al., 2004).

Thoracolumbar fractures can be associated with conus medullary injury (fractures from T8-L2) and cauda equina injury (fractures below L1-L2) (Brouwers et al., 2017).

Both syndromes are difficult to be distinguished one by the other. CMS is often characterized by a symmetric sensory deficits, bladder and bowel disfunction, and mild lower extremity weakness. CES is often defined by asymmetric sensory and motor deficits. In 20% of patients a complete lack of sensory and motor function will be present below the level of injury (Pickett et al., 2006).

Thoracolumbar SCI will show the same rate of neurological recovery of complete cervical SCI (Zariffa et al., 2011) After 1 year from trauma, patients will experience a mean recovery of 4.5 motor score points below injury level (Dvorak et al., 2014).

Surgical procedures

SCI are a wide spectrum of injuries, ranging from less to more severe spinal cord damage. For this reason, a singular approach to the spine is not correct and surgical choice should be individualized to each patient (Gargiulo et al., 2019; Girardo et al., 2018). The main goals of treatment are fixation of instability and decompression of the spinal cord (Fig. 2) and the choice of the correct surgical procedure is based on severity, level and mechanism of injury; location and extension of compression and surgeon preference.

Surgical approaches to the spine are classified as anterior or posterior. With both approaches stabilization and decompression can be achieved, but in more severe cases where a circumferential arthrodesis is needed, both approaches are combined together (staged or in single setting) (Bose, Osterholm, Northrup, & Cotler, 1985).

In cervical SCI, anterior approach is the most widely used allowing easily a ventral decompression and corpectomy, while a posterior approach is more appropriate for the thoracolumbar spine, where chest and abdomen represent an anatomical barrier.

In most cases, due to complex injury with disruption of anterior and posterior elements, anterior and posterior approach where combined together to perform a 360° arthrodesis.

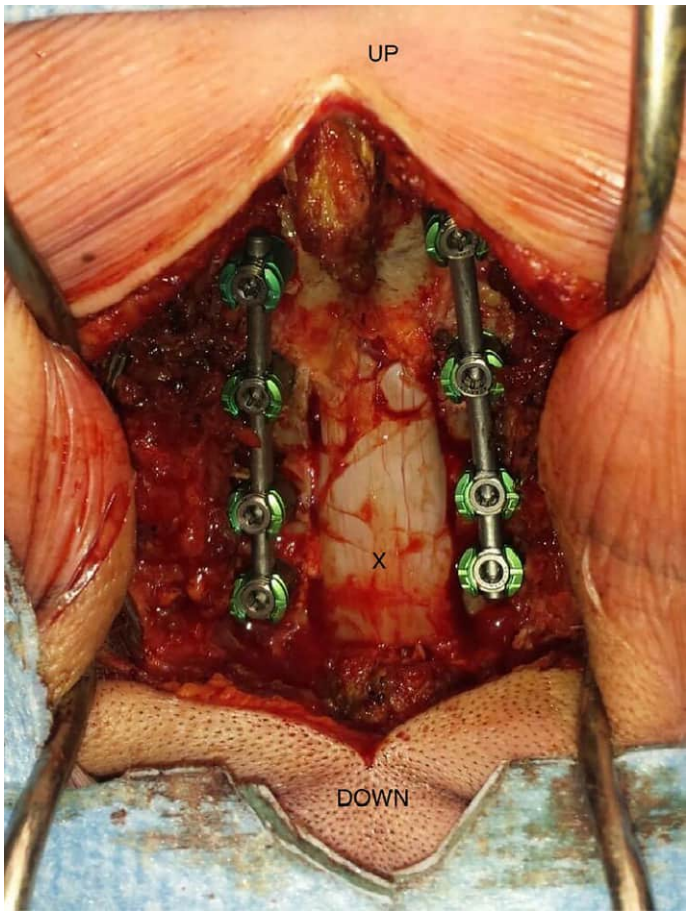

FIG. 2 Intraoperative picture about surgical decompression and fixation with screws and bars. In this picture the medulla (marked with "X") was decompressed and the cervical column was stabilized with screws and bars. "UP" and "DOWN" are referred to the patient head position.

Most common instrumentation devices used are pedicle screws with or without cement augmentation for thoracolumbar spine and pedicle or lateral masses screws for cervical spine. Usually, in acute traumatic SCI only one or two vertebral segments are involved and short segment stabilization is always preferred if possible. In flexion type injuries, posterior approach is usually preferred in the most of thoracolumbar injuries. In most cases, laminectomy, assure quick spinal decompression and also reduction with ligamentotaxis for thoracolumbar fractures (Feuchtbaum, Buchowski, & Zebala, 2016; Girardo et al., 2018) (Fig. 3).

How to define early versus late surgery post SCI?

Several articles have examined a different post injury range of time thresholds to define early versus late surgery. However, how much time can be considered "early" in not already clearly established. To recommend one of these thresholds and to choose the most favorable moment, two main principles must be considered (Fehlings & Sekhon, 2001; Wilson et al., 2017):

(1) efficacy (the extent of time in which surgery results in better outcomes).
(2) feasibility (the extent of time in which it is possible to perform surgery before the said limit taking into account the practical realities of the prehospital and hospital environment).

Which is the most efficacious threshold?

The theoretical objective of surgery is to begin a neuroprotective therapy performing a post injury treatment as soon as possible, preventing a secondary injury and favoring better recovery.

According to literature (Wilson et al., 2020), three common time thresholds can be found:

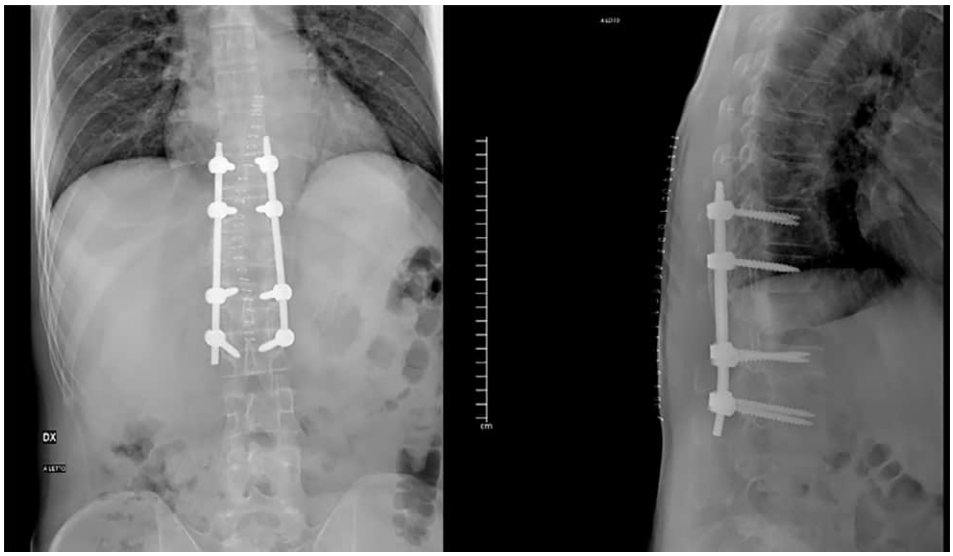

FIG. 3 X-rays about surgical treatment of SCI. About the same case of Fig. 1. The patient underwent ultra ESD with T10-L2 fixation with screws and bars.

(1) ultra-early threshold (8–12 h post SCI).
(2) early threshold (24 h post SCI).
(3) late threshold (48–72 h post SCI).

Ultra-early threshold (8–12 h post SCI)

Jug et al. evaluated the neurological outcomes of 48 patients who underwent surgery before 8 h and between 8 and 24 h post-injury. After 6 months from injury, patients treated <8-h showed a greater median improvement in ASIA motor score and a higher likelihood of improve of at least 2 AIS grade (Jug et al., 2015).

Grassner et al. evaluated the impact of surgery on functional outcomes in 70 patients who underwent SD prior to 8 h at 1 year follow up. The Authors analysis showed that patients receiving surgery prior to 8 h had superior scores and better motor outcomes at follow-up (Grassner et al., 2016).

In another study, 48 patients were retrospectively categorized into three groups depending on the timing of surgery: ultra-early (<12 h), early (12–24 h), and late (>24 h). Authors found a mean significant improvement of 1.3 AIS grade in ultra-early surgery group as compared with the mean improvement of 0.5 of patients who underwent early surgery (Burke et al., 2019).

Early threshold (24 h post SCI)

STACSIS highlight the role of early surgery in cervical SCI, showing greater neurological recovery, with 2 AIS grade improvement at 6 months of follow up (Van Middendorp, Hosman, & Doi, 2013). On another study focused on thoraco-lumbar SCI, Rahimi-Movaghar et al. didn't reach the same conclusion. In fact, despite the study lack some power, the difference between early and late surgery were not statistically significant (Rahimi-Movaghar et al., 2009).

In the comprehensive study of Dvorak et al., early surgery for all anatomical level reached significantly greater motor recovery. However, the same effect was not demonstrated in complete SCI (Dvorak et al., 2015).

In the Ontario-based cohort study, early surgery showed a higher likelihood of a 2 AIS grade improvement with a trend of additional improvement in motor recovery (Wilson et al., 2012).

It must be acknowledged that the 24 h cut-off is biologically arbitrary and it has been proposed for practical purpose; nothing changes between 23 and 25 h. So, when interpreting literature, it is important to remind that surgery is more effective when performed earlier but 24 h is only a threshold.

Late threshold (48–72 h post SCI)

Vaccaro et al. evaluated 64 SCI patients who received SD before 72 h after SCI or later than 5 days. At 1 year of follow up, the two groups didn't show any statistically difference in AIS grade conversion and motor score recovery (Vaccaro et al., 1997).

McKinley et al., reported the result of a study with a large sample of 779 patients from Model SCI Systems database and divided patients on the basis of SD prior or post 72 h. Authors found shorter hospital stay and reduced respiratory complications in patients who underwent SD before 72 h; however, no difference was found for neurological recovery (McKinley, Meade, Kirshblum, & Barnard, 2004).

Clohisy et al. evaluated 20 patients with thoracolumbar junction SCI. They found that patients surgically treated before 48 h showed grater improvements in neurological recovery than patients treated later. However, in this study patients who receive later surgery were treated about 2 months after injury (Clohisy, Akbarnia, Bucholz, Kenneth Burkus, & Backer, 1992).

What threshold is feasible?

Despite the common objective is to promote early treatment, the reality of daily life trauma care, from prehospital support to emergency department access, carry on several barriers.

For many reasons, including hospital transport, patient stability and diagnostic delays, only 50% of patients would be eligible to undergo SD before 24 h while other 50% of patients, in most cases underwent SD between 24 and 48 h (Tator, Fehlings, Thorpe, & Taylor, 1999).

The analysis of the CRHSCIR reported that in only 39% of cervical SCI and 45% of thoracic SCI, spine surgeons were able to perform SD before 24 h from trauma. Some Authors suggested that to improve early surgery rate, it is necessary to reduce barriers to early surgery in order to optimize patient outcomes (Dvorak et al., 2015).

Despite about 90% of patients arrived at the site of definitive treatment within 6 h of trauma, only 50% of them are able to undergo surgical treatment within 24 h. Older age and intermediate stop in peripheral health centers, prior to arrival in specialized center, were important factors for delay of surgery (Wilson et al., 2016) (Battistuzzo et al., 2016).

To support this findings, Furlan et al. reported that those patients who receive an early treatment (<24 h) spent less time in intermediate center before the arrival to definitive center (Furlan, Tung, & Fehlings, 2013).

In common practice, when patients access emergency department, they should be screened for any life threatened pathology, which must be treated first, since SCI is commonly associated with high energy trauma. For that reason, it is difficult to believe that most surgeries could be performed before 24 h from injury.

Does ESD offers the same benefit for all acute SCI?

SCI offers a wide spectrum of neurological impairment, from minimally to significant disabling, with a wide variability due to injury severity and neurological level of injury.

We will evaluate the current evidences about the efficacy of ESD in acute SCI based on level and severity of injury and time of surgical intervention.

Complete versus incomplete SCI

In literature, only few studies have examined the role of ESD in complete and incomplete SCI. Dvorak et al. evaluated 888 patients recruited in the CRHSCIR. In this study, attention was focused on the significant role of early surgery (<24 h post SCI) on motor recovery and the Authors concluded as ESD was not associated with significant improvements in motor function. However, considering only patients with incomplete SCI graded as ASIA B-D, ESD was associated with an improvement of 6.3 points in motor score recovery at 6 months follow-up. As expected, no significant effect for ESD was observed in grade A patients (Dvorak et al., 2015).

Bourassa-Moreau et al. examined a cohort of SCI. He found a 34% of AIS improvement of ESD (<24 h) and 13% of improvement in late surgery (>24 h), with even a higher difference for cervical SCI (64% versus 36%). Moreover, they didn't observe any conversion in AIS grade for complete SCI between early and late surgery (Bourassa-Moreau et al., 2016).

More recently, Ma et al. analysed in their meta-analysis the effects of ultra ESD (<8 h) on patients with acute SCI. He found more significant improvement in AIS score than in patients treated with early (8–24 h) or late (>24 h) surgery.

Patients had more benefits in neurological recovery from ultra ESD with no difference in hospital stay and rate of complications (Ma et al., 2020).

On the other hand, ESD (<24 h after injury) reduced hospital stay, especially for patients with complete SCI (Dvorak et al., 2015).

All studies were in accordance regarding the benefits of ESD also for what concern the length of hospital stay for patients with complete SCI, while no other study support the benefit of ESD for incomplete SCI (Bourassa-Moreau, Mac-Thiong, Feldman, Thompson, & Parent, 2013; Mac-Thiong, Feldman, Thompson, Bourassa-Moreau, & Parent, 2012).

Unfortunately, there are no large prospective studies that confirmed the superior effects of ESD on neurological outcomes for incomplete versus complete SCI. These findings are supported by the hypothesis that for incomplete SCI, the primary energy of injury is not so powerful to cause a complete SCI, and there may be greater potential for neuroprotection (Dvorak et al., 2015) (Bourassa-Moreau et al., 2016).

Effects of ESD on different neurological level of injury

One of the most important factors in patients with SCI is the neurological level of injury, which can influence patients' potential recovery (Wilson et al., 2012).

However, there are no many studies focused on specific neurological level and the effect of early or late surgery on neurological recovery. Commonly, cervical and thoracolumbar SCI are reported together and data are difficult to be extracted for each neurological level.

Effect of SD in patients with cervical SCI

STASCIS is the largest study involving patients with only cervical SCI (Fehlings et al., 2012). Authors of this study analysed several cervical SCI undergoing either early (<24 h) or late (>24 h) SD and compared AIS grade changes at 6 months follow up. Both groups underwent at least 1 grade; however, patients treated with early surgery are more likely to improve AIS of 2 grade or more (odds ratio 2.57; $P = .01$), than patients who underwent late surgery. No differences between groups were found in term of complications, despite the trend is in favor of ESD (24% versus 30% respectively) (Van Middendorp, 2012).

More recently, Aarabi et al. evaluated 72 patients with traumatic cervical SCI with AIS grade A, B or C. Patients were stratified on the basis of ultra-early (<12 h), early (<24 h) and late (>24 h) surgery. Improvement of one grade or more was present in 55.6% of grade A, 60.9% of grade B, and 86.4% of grade C patients, but not in a significant manner. Authors also found other crucial predictive factors that could be more likely associated with injury recovery such as admission motor score and intramedullary lesion length (Aarabi et al., 2020).

Effect of SD in patients with thoracic and thoracolumbar SCI

Rahimi-Movaghar et al. evaluated 35 patients with thoracic and thoracolumbar (T1-L1) SCI. Some underwent early (<24 h) while other late (>24 h) surgery. There was no difference between motor score recovery at 12 months of follow up, considering both complete and incomplete SCI (Rahimi-Movaghar et al., 2009).

In the NACTN for SCI, researchers evaluated 86 patients with SCI and neurological injury between T1 and L1. Early surgery (<24 h) was associated with additional seven points of ASIA motor recovery and a reduction of 60% in pulmonary complications (Wilson et al., 2018).

Effect of SD on miscellaneous SCI

Some studies reported cervical, thoracic and thoracolumbar SCI as a unique entity; we report them in this section since it is not possible to revise the results and divide them in anatomical region.

In the study of Bourassa-Moreau et al., patients treated with early surgical decompression (<24 h) showed improved rates of AIS conversion among cervical AIS grade A, while the same was not reported for thoracolumbar trauma (Bourassa-Moreau et al., 2016).

The Ontario-based cohort study involved 84 patients with all levels of SCI. Patients treated surgically prior to 24 h didn't show a significant increasing trend in motor recovery at rehabilitation discharge. Authors found the level of injury to be a significant predicting factor for neurological recovery, but they didn't investigate if the effects of ESD vary with level of injury (Wilson et al., 2012).

In the study of Dvorak et al., despite the impact of surgery was not analysed, it appears that patients with incomplete SCI from all anatomical level benefit from ESD (Dvorak et al., 2015).

The special case of Central Cord Syndrome

Central Cord Syndrome (CCS), the most frequent type of incomplete SCI, was first described by Schneider in 1954; it is characterized by involvement of the four limbs but with greater motor and sensitive deficits in upper extremities. Commonly, it is often secondary to low energy trauma especially in elderly patients where a pre-existing spinal stenosis (Schneider & Knighton, 1959; Schneider, Thompson, & Bebin, 1958) (Fig. 4).

The natural history of neurological recovery for CCS has been generally favorable. Most of patients well able to walk independently, without supports, with normal sphincteric function at long term follow-up (Dahdaleh et al., 2013). For that reason, conservative treatment had been historically the gold standard in CCS, while early operative intervention might derail this otherwise favorable natural history. This concerns find their foundation in Schneider's original description of CSS, where one patient had a worsening of neurologic injury after acute surgical treatment (Schneider, Cherry, & Pantek, 1954).

Despite early surgery is gaining popularity as the preferred approach for treatment of SCI, practices surrounding the time of surgery remains undefined. Currently, many surgeons continue to adhere to historical practice (Fehlings, Rabin, Sears, Cadotte, & Aarabi, 2010). In fact, in a recent survey, only 44% of attendants preferred to operate within the first 24 h from injury (Ter Wengel et al., 2018).

Currently, despite only few high-quality studies are about this topic, the best evidence found in international literature support the practice of early surgery.

Lenehan et al. evaluated the impact of surgical timing on clinical outcomes in patients with CCS. Patients were divided in early and late surgical group according to surgical intervention time, prior or post 24 h from injury. Patients treated early, experienced 6.3 points more of motor recovery and had about three times more of AIS grade conversion than late surgery. The same was observed for patients who underwent ESD with no significant perioperative morbidity (Lenehan et al., 2010).

Despite the huge historical significance, the surgical approach of Schneider, who performed a posterior direct intradural approach to cervical disc, would not be acceptable today. With better and improved surgical techniques and technologies, surgery can be performed effectively and safely.

Although natural history of CCS is favorable for ambulation, motor recovery and sphincter function, it must be acknowledge that some patients could suffer from neuropathic pain, ongoing spasticity and impairments in hand dexterity (Dvorak et al., 2005).

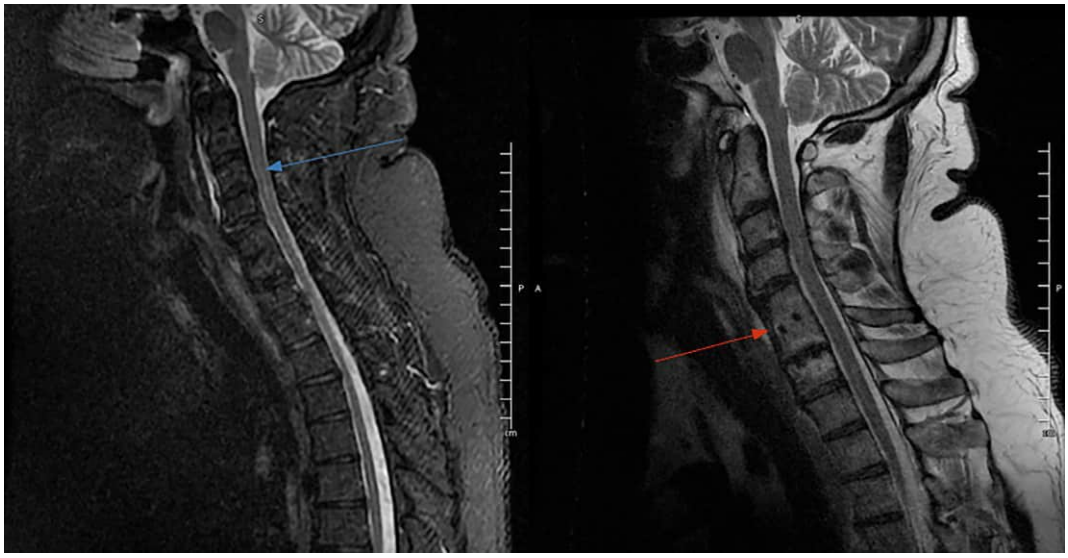

FIG. 4 Clinical case of Central Cord Syndrome (CCS). In this picture STIR *(left)* and T2 *(right)* MRI sequences of a CCS clinical case. The patient (50 years old; man) arrived after a motorcycle accident. On the left, marked by the *blue arrow*, hyperintensity can be seen (Central Cord Syndrome lesion). In this specific case the lesion occurred over a rigid cervical spine segment marked by the *red arrow* (previous arthrodesis).

Conclusions

Surgical treatment of SCI is important to avoid the secondary mechanism of injury related with vascular impairment and ischemic damage. Natural history of complete cervical SCI is characterized by an absence of improvement for the majority of cases, while in patients with incomplete SCI, the chance of natural neurological improvement is significant higher. Complete thoracic SCI shares the same rate of improvement of complete cervical SCI; however, thoracolumbar SCI has lower motor score recovery than cervical SCI.

Surgical treatment is performed through SDSF; anterior, posterior or combined approach depends of the level of injury, extension of compression and surgeon preference.

According to literature, surgical treatment can be performed ultra-early, early or late, depending of time passed from injury. At the moment early treatments offers superior results.

Despite earlier is better, it's extremely difficult to undergo surgical intervention before 8 h from trauma. This difficulty is connected to transport from place of injury to reference center for spinal injury, injury assessment, patient stability and other life-threatening pathologies. For this reason, the most suitable and realistic time of intervention balancing surgical risks and better outcomes should be set before 24 h.

Applications to other areas of neuroscience

In this chapter, we have reported a review about efficacy and effectiveness of SD for the treatment of SCI. This kind of surgery also has an important role for the treatment of CSM caused by spondylosis or ossification of the posterior longitudinal ligament (Boogaarts & Bartels, 2015). This pathology usually affects people aged over 50 years old causing progressive dysfunction and disability. The principal symptoms that may be found are weakness in upper and lower body, numbness, clumsiness, and difficulty handling. Posterior decompression is the most accepted treatment for CSM and it plays a crucial role like decompression for SCI (Singrakhia, Malewar, Singrakhia, & Deshmukh, 2017). The treatment aims to reduce stress and forces that attack spinal cord and medulla driving to ischemic troubles and lesions. Unlike decompression for SCI, the CSM one is usually performed posteriorly and may be performed with or without segment fixation. In fact, despite the indication of posterior decompression surgery without segment fixation is rarely performed; some Authors reported this technique as a valuable, easier and faster surgical approach in patients strictly selected on the base of preoperative cervical alignment or segmental stability (Gargiulo et al., 2019). However, the correct indication about fixing or not fixing is actually debated in literature.

Mini-dictionary of terms

- Spinal Cord Injury: A damage to the spinal cord.
- Complete spinal cord injury: Damage to the spinal cord in which the nerves below the level of injury cannot communicate with the brain anymore
- Incomplete spinal cord injury: Damage to the spinal cord in which the nerves below the level of injury can still sent some signals along the spinal cord. The clinical pattern of movement and sensation may vary a lot among patients
- Tetraplegia: Also known as quadriplegia, it is the paralysis that results in the partial or total loss of use of all four limbs.
- Paraplegia: Paralysis that results in the partial or total loss of use of the lower limbs.
- Central Cord Syndrome: Most common form of SCI; characterized by loss of motion and sensation in arms while the lower limbs result to be normal
- Anterior Cord Syndrome: It is caused by ischemia of the anterior spinal artery that lead to the complete loss of function of the anterior spinal cord with motor function loss associated to loss of pain and temperature sensation.
- Cauda Equina Syndrome: Serious neurologic condition characterized by low back pain that radiates down the leg associated with numbness around anus and loss of bladder and anus control. This condition affects only lower motor neurons.
- Conus Medullaris Syndrome: It is a subset of SCI caused by injuries that involve the tract between T12 an L2. Very similar to Cauda Equina Syndrome (CES), but unlike CES a combined involvement of upper and lower motor neuron may be found.
- Brown-Sequard Syndrome: Rare neurological condition characterized by hemiplegia and hemianesthesia affecting two opposite side of the body

- Surgical Decompression: Surgical procedure that is usually performed to alleviate pain caused by pinched nerves. In case of SCI, surgeons may perform this procedure to alleviate the compression forces that damage the spinal cord.
- Posterior stabilization: Surgical procedure that consists in stabilize the spine through a posterior surgical access. The hardware most used are screws and bars.
- ASIA scale: Universal classification tool for spinal cord injuries based on standardized sensory and motor assessment.

Key facts of surgical treatment of spinal cord injury

- Wait and see approach is not recommended
- SD granted oedema reduction, compression removal, blood supplies improvement and neuronal apoptosis inhibition
- ESD (<24 h) of SCI improved neurological symptoms
- Ultra ESD (<6 h) ensure better chance of spinal cord recovery; however, no later than 24 h decompression is recommended, since life treating condition could delay SD
- SD of Central Cord Syndrome is still controversial; the more recent literature support early surgical decompression

Summary points

- In SCI the persistent compression derived by the first injury may inexorably drive to a second injury.
- Low ASIA scale scores at injury are related with worse prognosis. Approximately 85% of ASIA scale grade A patients at injury will not improve their neurological status at 1 year of follow up.
- Thoracic SCI improve less than cervical and lumbar ones.
- Surgery has two main objectives: to fix and to decompress.
- Three common time thresholds are described in literature: ultra-early threshold (8–12 h post SCI), early threshold (24 h post SCI) and late threshold (48–72 h post SCI).
- Anterior and posterior approaches to the spine may be adopted. Posterior ones are preferred in thoracolumbar spine.
- Earlier decompression surgery may guarantee better rate of neurological improvement.
- In CCS patients, decompression efficacy is debated.

Introduction

Spinal cord injury (SCI) affects nearly 2 million people in the United States (Reeve Foundation Paralysis Resource, 2021) and results in profound neurologic impairment with widespread deficits to sensorimotor and autonomic systems. While the lack of ambulation is most widely recognized, there are many internal systems that are disrupted after SCI due to the critical role of the spinal cord in coordinating bodily functions. As a result, individuals with SCI endure a myriad of complications that result in increased mortality, morbidity, hospitalization, high burden of care and health care costs, and a drastically lowered quality of life (Merritt, Taylor, Yelton, & Ray, 2019).

The autonomic nervous system serves to provide essential regulatory communication between the brain and internal organs, vascular supply, and numerous glands in order to maintain dynamic equilibrium and homeostasis of all systems. Sympathetic and parasympathetic systems (including the enteric system for the gastrointestinal tract) function to integrate complex reflex pathways between the target organ and integration centers within the nervous system (Gibbins, 2013). Thus, autonomic disruption extends across multiple systems and drastically impacts overall health and quality of life. Alterations of urogenital and bowel dysfunctions are consistently rated as top consumer priorities for recovery post-SCI (Anderson, 2004; Ditunno, Patrick, Stineman, & Ditunno, 2008; Simpson et al., 2012). Acutely post-SCI, bladder dysfunction often manifests as "flaccid paralysis," resulting in urinary retention necessitating bladder catheterization. Overtime, bladder dysfunction progresses into detrusor hyperreflexia and detrusor-sphincter dyssynergia, resulting in incontinence and incomplete emptying. Gastrointestinal disruptions after SCI are highly prevalent and include a wide-range of symptoms, including delayed gastric emptying, diminished propulsive transit, abdominal distention, pain, constipation, anal fissures, hemorrhoids, rectal prolapse, and sphincter/defecation disturbances (Krogh et al., 1997). Cardiovascular dysfunction associated with autonomic dysregulation contributes to increased morbidity and is the leading cause of mortality in acute and chronic SCI (Devivo, Krause, & Lammertse, 1999). The disruption of supraspinal control over sympathetic pathways

Diagnosis and Treatment of Spinal Cord Injury. https://doi.org/10.1016/B978-0-12-822498-4.00018-X

results in decreased sympathetic tone below the level of injury and impaired autonomic function and blood pressure regulation (Koh, Brown, Beightol, Ha, & Eckberg, 1994). One critical complication that occurs in individuals with lesions above T6 is autonomic dysreflexia (AD), an exaggerated sympathetic nervous system response to a noxious stimulus below the level of injury, including bladder/bowel distention, urinary tract infections, fecal impaction, and orgasms (Karlsson, 1999). As a result, increased cardiovascular dysregulation has a profound effect on the body as a whole and significantly interferes with motor and autonomic recovery post-injury.

Bladder dysfunction after SCI

Long-term deficits in bladder function after SCI manifest as detrusor hyperreflexia (bladder contractions at low volumes, causing incontinence and smooth muscle hypertrophy), detrusor-sphincter dyssynergia (uncoordinated bladder and external urethral sphincter contractions, causing inefficient emptying and smooth muscle hypertrophy), decreased compliance (unable to store urine under appropriately low pressures) and loss of continence (Fig. 1) requiring lifelong management, maintenance, and health care visits (Stover, Devivo, & Go, 1999). Major urological concerns contributing to increased morbidity and mortality include repeated lower urinary tract infections that can lead to sepsis, chronic vesico-ureteral reflux and hydronephrosis with progression to renal failure as a result of high-intravesical pressures, and inter-related cardiovascular complications such as AD (Hagen, Faerestrand, Hoff, Rekand, & Gronning, 2011) that

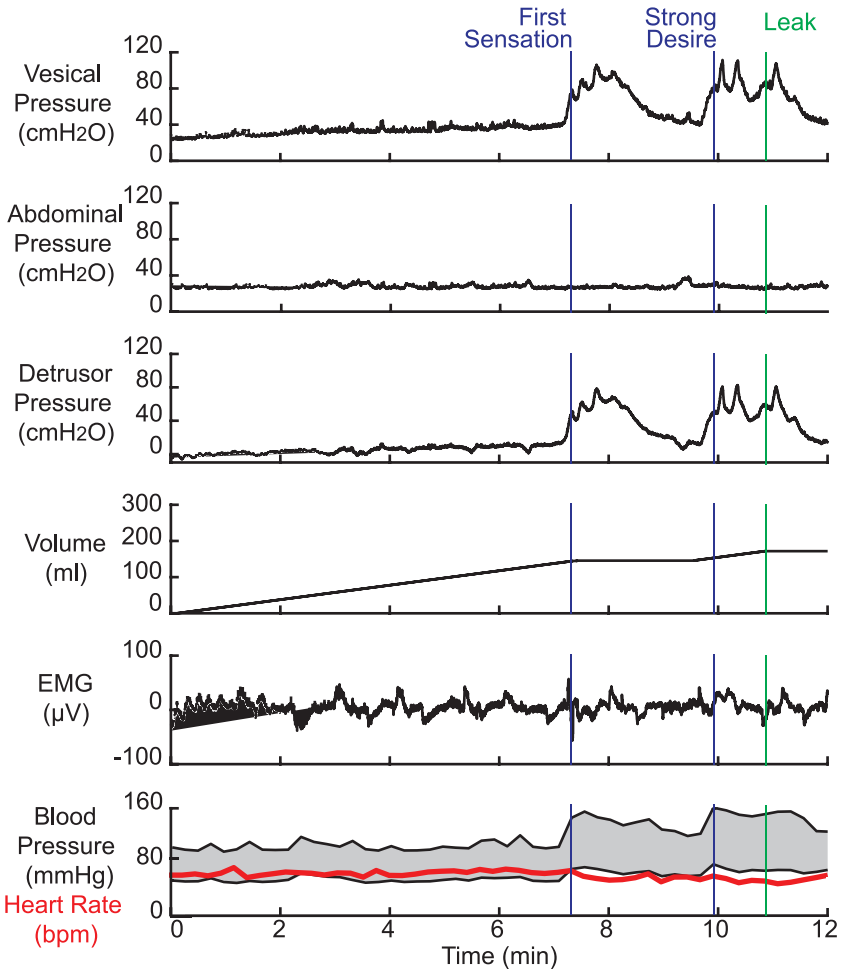

FIG. 1 Neurogenic bladder dysfunction. Representative cystometry recording, including vesical pressure (cmH_2O), abdominal pressure (cmH_2O), detrusor pressure (cmH_2O), volume of infused saline (Ml), surface electromyography (EMG, μV) of the external anal sphincter, continuous blood pressure (mmHg), and heart rate (red, bpm) responses in a 26-year-old male (C4, AIS B), who performs intermittent catheterization for bladder emptying. Multiple detrusor contractions are present, resulting in incontinence at 171 ml with detrusor leak point pressure of 58 cmH_2O. The rise in blood pressure was timed with the rise in detrusor pressure.

limits bladder storage (Hubscher et al., 2018). Current therapies to improve the efficiency of bladder voiding, management and continence after SCI include catheterization, pharmacologic and surgical interventions, functional electrical stimulation, as well as urethral stents. In particular, neurogenic detrusor overactivity and detrusor sphincter dyssynergia are commonly managed with anti-muscarinic drugs and Botox injections, and while these pharmacotherapy agents do not prevent or reverse the changes, they primarily focus on improving storage outcomes and do not address the emptying phase. Furthermore, anti-muscarinic agents can have unpleasant side effects such as dry mouth and constipation, exacerbating existing bowel dysfunction. The primary goal in managing neurogenic bladder is to protect the upper urinary tract and reduce the incidence of infections, followed by achieving continence. As such, when conservative management fails, surgeries to reduce high bladder pressures and chronic urinary incontinence include urinary diversion and lower urinary tract reconstruction approaches (Biers, Venn, & Greenwell, 2012). As urinary complications continue to impact long-term morbidity in this population, additional therapeutic and rehabilitative approaches are needed that aim to improve function by targeting the recovery of underlying impairments.

Bowel dysfunction after SCI

Complications with bowel storage and evacuation are highly prevalent after SCI, with 95% of patients reporting issues with constipation (Glickman & Kamm, 1996). Also, 75% report episodes of fecal incontinence with 30% considering bowel disorders more burdensome than bladder (Krogh et al., 1997) and having a substantial negative impact on quality of life, social integration, and overall independence (Emmanuel, 2010). Neurogenic bowel dysfunction can be characterized by the presence of increased colonic wall and anal tone along with weak abdominal musculature, resulting in fecal retention and constipation. A significant risk of incontinence can occur from an inability to adequately engage the external anal sphincter and pelvic floor musculature (Stiens, Bergman, & Goetz, 1997). While gastrointestinal transit is primarily influenced by local enteric reflexes, motility patterns can be modulated by extrinsic innervation derived from sympathetic, parasympathetic and vagal inputs. Due to difficulties with elimination, prolonged colonic transit time, and impaired motor dexterity (Longo, Ballantyne, & Modlin, 1989), large amounts of time are devoted to bowel care programs (for some, up to 2 h) (Glickman & Kamm, 1996; Hubscher et al., 2018). Many individuals with SCI are also dependent on caregiver assistance. As a result, many choose to conduct their programs every other day (Kirshblum, Gulati, O'connor, & Voorman, 1998), which may increase the risk of constipation, fecal impaction, colorectal distension, and episodes of AD. Conservative bowel regimen approaches include the use of laxatives and stool softeners to obtain a desired consistency, followed by rectal stimulation with either suppositories, enemas, or digital stimulation. Digital stimulation involves rectal pressure with a gloved finger to activate the recto-colic reflex, generating coordinated colonic peristaltic activity and increased motility (Shafik, 1996). Consequently, there is tremendous interest to use neuromodulatory strategies to achieve same or better effects.

Cardiovascular dysfunction and interactions with other autonomic systems after SCI

Cardiovascular diseases are the leading causes of morbidity and mortality among the SCI population (Wecht et al., 2020). Hemodynamic and metabolic cardiovascular effects occur in both the acute and chronic phases of SCI. Disruptions of sympathetic pathways to the heart and vasculature cause autonomic dysfunction and baroreflex impairment resulting in a reduced ability of cardiovascular system to maintain stable blood pressure after SCI. Dysregulation leads to persistent hypotension, bradycardia, orthostatic hypotension, and episodes of AD which drastically impacts quality of life by affecting health and disrupting engagement in daily activities (Krassioukov, Eng, Warburton, & Teasell, 2009). Combinations of sympathetic agonists and venous compression devices are the primary measures currently used for symptomatic management. Manifestations of the reduced quality of life experienced is evidenced by reductions in peripheral blood flow, resulting in an increased risk of pressure ulcers, parasympathetic imbalance increasing vasovagal syncope, fatigue and cognitive dysfunction, and symptomatic orthostasis (Wecht & Bauman, 2018). With time, post-injury blood pressure instability becomes more prominent and persists in many individuals with SCI for the rest of their lives (Katzelnick et al., 2019). AD, characterized by episodes of acute hypertension, is generated by unmodulated sympathetic reflexes below the injury level, and is typically accompanied by compensatory baroreceptor-mediated bradycardia (Karlsson, 1999). Distention or contraction of hollow organs, such as bladder and bowel, are the most common triggers of AD (Lindan, Joiner, Freehafer, & Hazel, 1980). Such below-level peripheral afferent stimuli reach the isolated spinal cord and activate a massive unmodulated sympathetic reflex causing widespread vasoconstriction, presenting as severe hypertension. With high-level SCI, the additional interruption of descending modulatory autonomic pathways that normally inhibit sympathetic preganglionic neurons during hypertension allows AD to persist until the stimulus is removed (Rabchevsky, 2006) (Fig. 2). Management

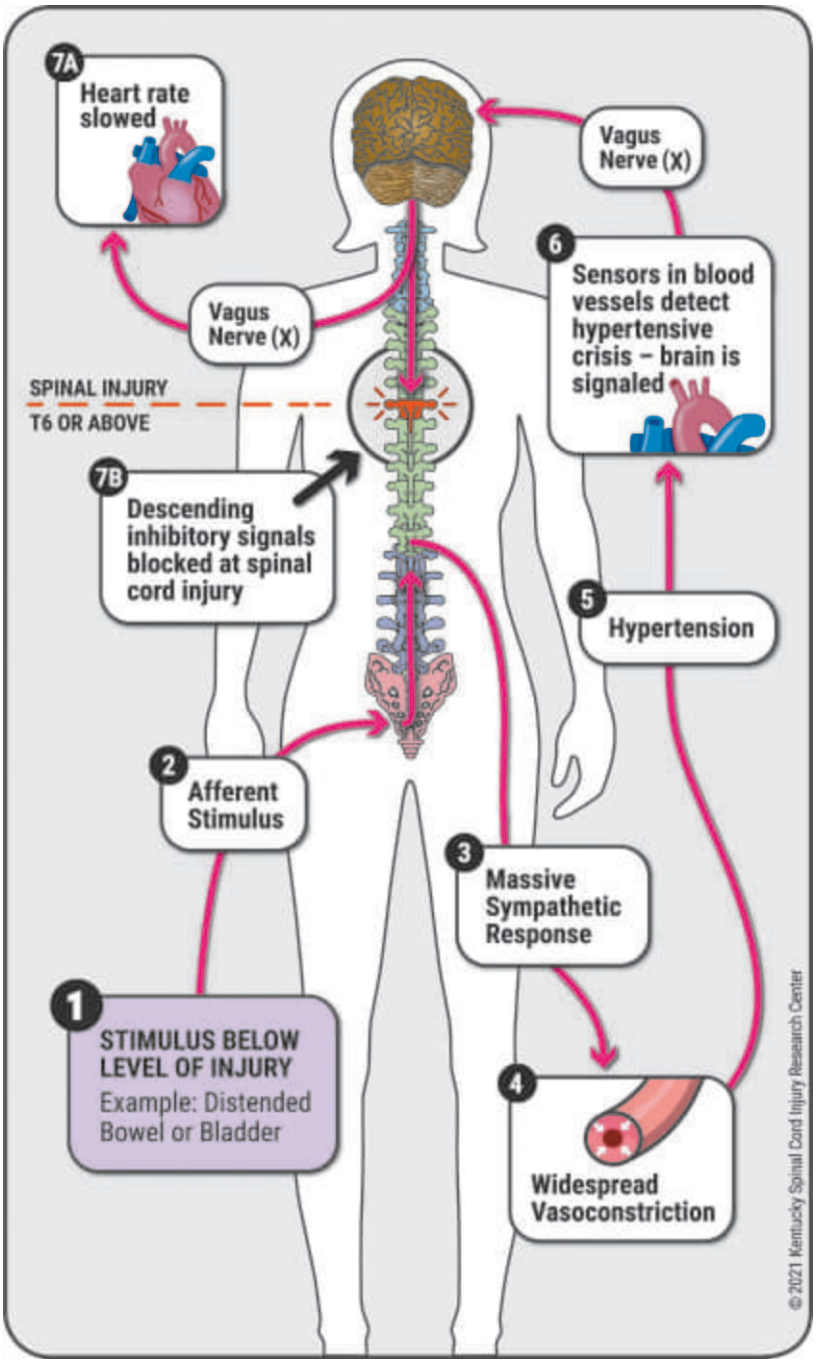

FIG. 2 Autonomic Dysreflexia after SCI. Cartoon diagram outlining the cascade of events leading up autonomic dysreflexia. Primary precipitating stimuli for autonomic dysreflexia include bladder and/or bowel distention.

and mitigation of unstable blood pressure is therefore a high consumer priority in SCI care; however, therapies available that have demonstrated the ability to resolve chronic cardiovascular dysfunction are lacking (Wecht et al., 2020; Wecht, Cirnigliaro, Azarelo, Bauman, & Kirshblum, 2015). With time, post-injury episodes of AD become more prominent and persist long-term. The ability to recover bladder function such as, increasing bladder capacity, minimizing detrusor instability and improving bladder pressure and emptying, is limited by such severe fluctuations in blood pressure. Furthermore, improvements in bowel function are challenged by regular occurrences of AD symptoms during bowel programs, evoked by distention (Inskip, Lucci, McGrath, Willms, & Claydon, 2018) (Fig. 3). The extreme dysregulation of the cardiovascular system underscores the importance of addressing these multi-faceted autonomic complications.

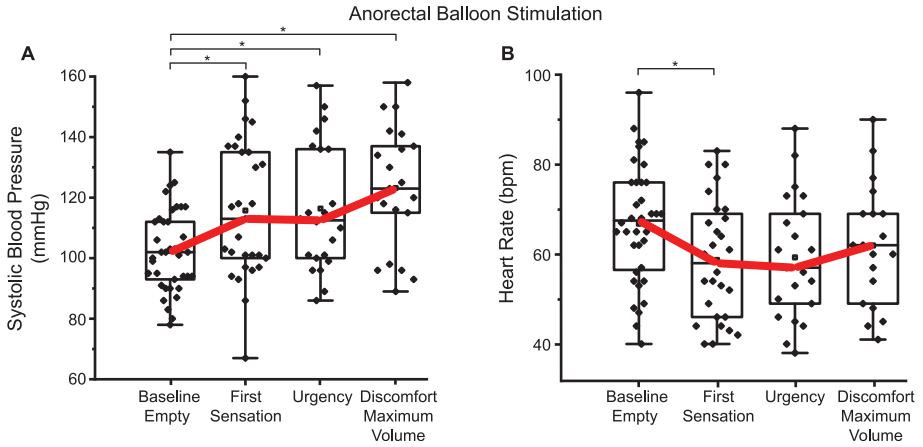

FIG. 3 Blood pressure responses to anorectal distention. Participants ($n = 37$) were asked to respond to sensations of rectal fullness associated with gradual inflation of a balloon catheter during anorectal manometry. Relative to baseline (prior to inflation), mean systolic blood pressure *(red line)* was significantly greater at first sensation ($n = 30$, $P < .01$), urgency ($n = 22$, $P < .05$), and maximum volume ($n = 21$, $P < .01$) (A), while mean heart rate *(red line)* was significantly lower at first sensation ($n = 30$, $P < .01$) relative to baseline (B). Note, while data are normally distributed, not every participant reported each sensation. The normative ranges for volume (mL) at which first, urgency, and maximum sensations of fullness occur are 10–60 mL, 10–100 mL, and 100–200 mL, respectively.

Introduction of spinal cord stimulation

Melzack and Wall's publication of the Gate Theory (Melzack & Wall, 1965) transformed our understanding of pain mechanisms and the associated clinical management, leading to the realization that pain was the result of complex dynamic processes in the nervous system and not simply the result of activity in a hard-wired system. The concept that damage to the nervous system can itself result in chronic pain led to a gradual shift from ablative and destructive surgical approaches, such as cutting nerves, toward reversible neuromodulatory strategies such as therapeutic electrical stimulation of the dorsal spinal cord. The theory that nociceptive impulses, carried by Aδ and C fibers, could be inhibited by electrical stimulation of thick myelinated Aβ fibers provided the first scientific basis for the use of stimulation for pain. At that time, implanted electrode-induced electrical stimulation of the dorsal columns was initially introduced in 1967 in an effort to treat chronic intractable pain (Shealy, Mortimer, & Reswick, 1967). Its use was expanded to treat a wide variety of pain disorders following improvements in sensorimotor function in the multiple sclerosis population (Cook & Weinstein, 1973) and was first used to treat neuropathic pain in SCI in the early 1970s (Nashold Jr. & Friedman, 1972; Shealy, Mortimer, & Hagfors, 1970). Subsequently, the US Food and Drug Administration (FDA) approved the use of spinal cord stimulation in 1989 for the treatment of chronic intractable pain of the trunk or limbs and now accounts for the majority of all neuromodulation interventions (Barolat & Sharan, 2000).

Initial applications of spinal cord epidural stimulation (scES), which served to clinically control severe spasticity in SCI (Dimitrijevic, Illis, Nakajima, Sharkey, & Sherwood, 1986), led to the examination of whether scES had the capacity to drive locomotor capabilities through excitation of the lumbosacral motor circuitry (Waltz, Andreesen, & Hunt, 1987). By activating sophisticated spinal networks below the level of injury, scES functions by reactivating spared neural pathways and bridging supraspinal connectivity across the lesion with the goal of improving recovery after SCI. In persons with motor complete SCI, rhythmic, locomotor-like EMG activity and tonic motor patterns of the lower limbs from the supine position (in the absence of afferent input) were induced with scES (Dimitrijevic, Gerasimenko, & Pinter, 1998). Harkema and colleagues then demonstrated that a critical level of excitability, provided by scES and coupled with intense training that provides appropriate task-specific sensory cues, was necessary to facilitate standing and stepping, as well as intentional movement in clinically motor complete SCI (Angeli, Edgerton, Gerasimenko, & Harkema, 2014; Harkema et al., 2011). The combination of locomotor training (stepping and standing) plus scES not only enhanced coordinated and controlled voluntary motor behavior, but was also reported by individuals to improve physiologic outcomes such as bladder, bowel, and sexual function (Darrow et al., 2019; Harkema et al., 2011; Herrity et al., 2020), as depicted in Fig. 4. A summary of spinal cord stimulation approaches is provided in Table 1.

Neuromodulation to improve bladder function

Many current and past neuromodulatory procedures have had variable success at sustained improvements of bladder function after SCI (McGee, Amundsen, & Grill, 2015; Wheeler et al., 2018). The Finetech-Brindley device (marketed

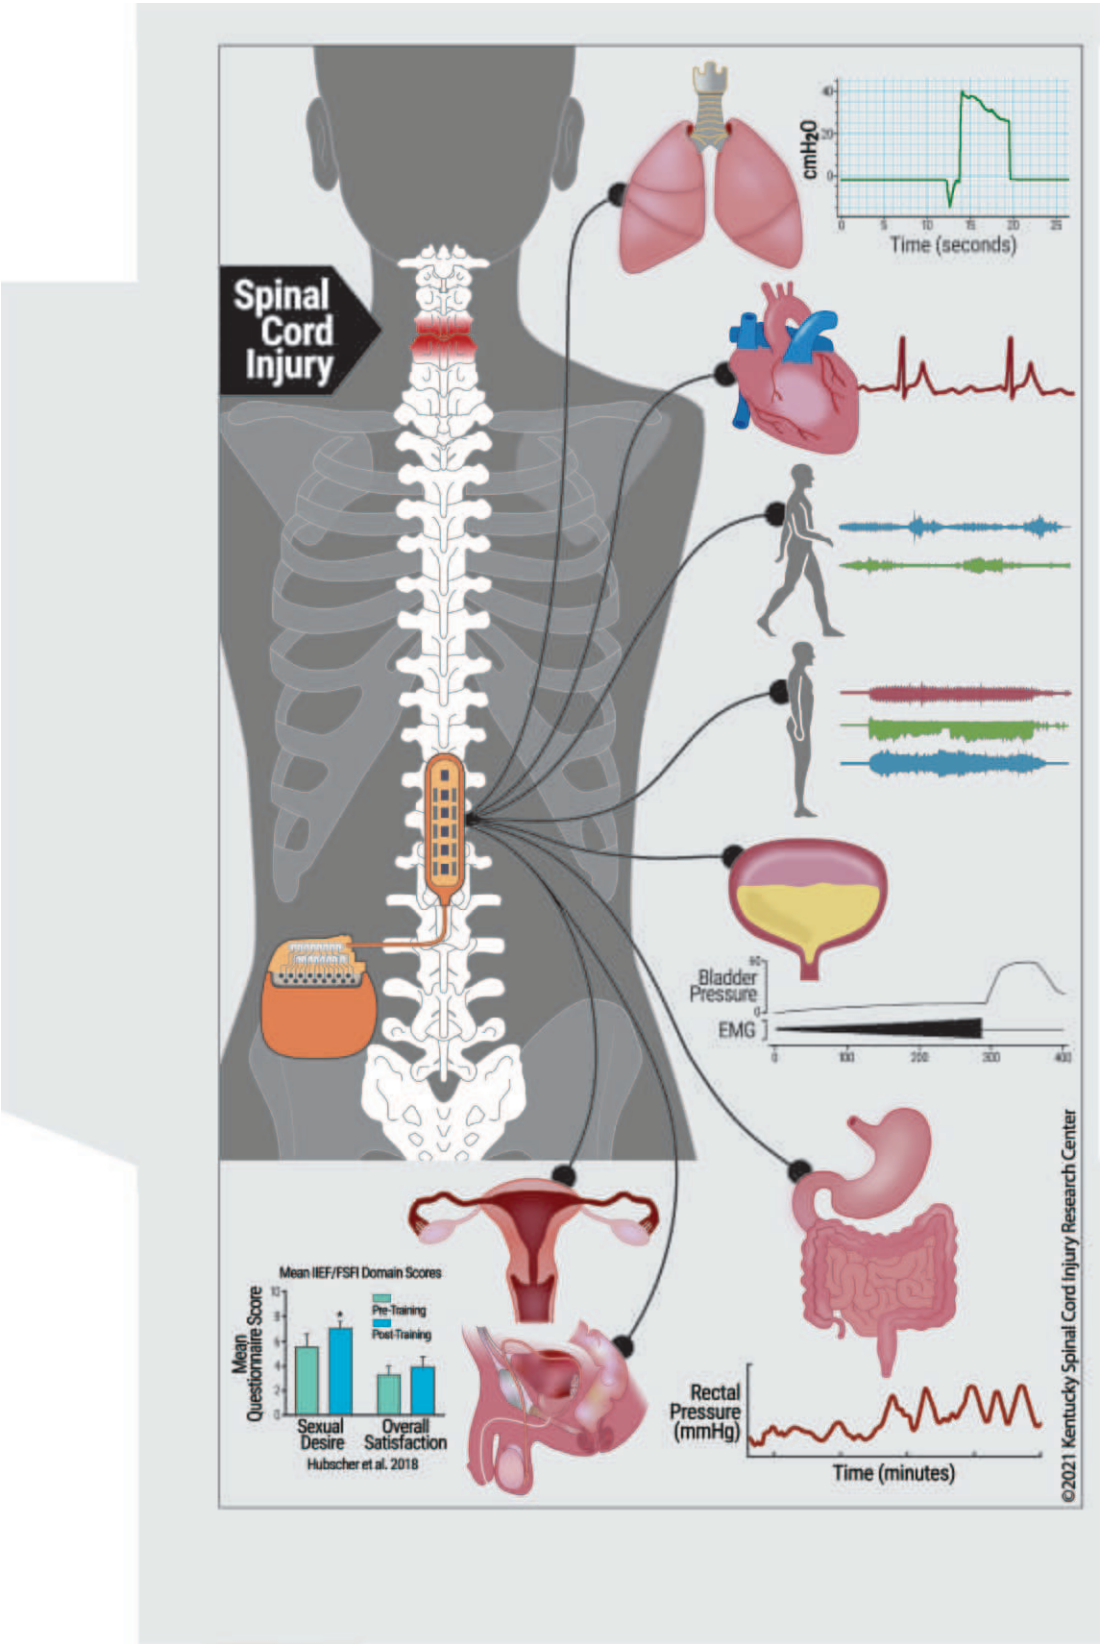

FIG. 4 Restoration of motor and autonomic function using scES. Cartoon illustration depicting some of the body systems targeted by scES. Device implantation in individuals with SCI currently involves placement of an electrode array at the lumbosacral segment of the spinal cord between L1 to S1. The location of the stimulation paddle electrode is guided by intra-operative fluoroscopy and electrophysiology mapping to identify segments of the spinal cord that respond to electrical stimulation. Following surgery, additional neurophysiological spatiotemporal mapping of various electrode configurations is performed.

in the United States as VOCARE Bladder System), designed to stimulate the anterior sacral roots (S2–S4), was used to aid voiding via intermittent stimulation bursts that maintained constant bladder pressure while periodically relaxing the urethral sphincter, allowing urine to flow in between stimulus intervals (post-stimulus voiding) (Brindley, 1994). Despite the clinical improvements in bladder emptying, one of the major accompanying limitations of the device stems from the irreversibility of ablating intact neural roots. Thus, a shift toward continuous or conditional neuromodulation was proposed in order to preserve the potential for future treatment options in patients with SCI (Hansen et al., 2005). Continuous sacral neuromodulation (applied most commonly over the S3 nerve root) is now a widely accepted stimulation modality for patients with refractory non-neurogenic lower urinary tract dysfunction, including, non-obstructive chronic urinary retention, urgency-frequency syndrome, and urge incontinence (Kessler et al., 2007). Initially, its use was not intended for those with neurogenic bladder dysfunction, but has shown some benefit for reducing detrusor hyperreflexia in those with incomplete SCI (Kessler et al., 2010). Note that peripheral nerves have also served as promising, minimally invasive

targets to modulate the bladder circuitry after SCI, especially for those who may not be appropriate candidates for sacral neuromodulation. However, the stimulation site is distant from the central nervous system and involves repeated applications that may limit long-term durability in the SCI population (Gaziev et al., 2013).

Lumbosacral scES may be an effective approach which mechanistically may involve indirect activation of the same neural networks for bladder function. Several pre-clinical studies have demonstrated that electrical stimulation at select spinal locations can modulate both reflex detrusor and external urethral sphincter activity to induce micturition in different conditions: non-injured rats (Sysoev et al., 2020), nerve crush injuries (Chang, Yeh, Ichiyama, Rodriguez, & Havton, 2018), and following SCI in rats (Abud, Ichiyama, Havton, & Chang, 2015; Hoey et al., 2021) and cats (Pikov, Bullara, & Mccreery, 2007). In the context of human studies using scES, unanticipated gains in bladder function were achieved following locomotor training, where stimulation was optimized for improving standing and stepping (Harkema et al., 2011). The effects of activity-dependent scES on bladder function was further tested in 10 participants enrolled in scES training studies relative to participants in usual care ($n = 10$) who continued their typical daily lives without any study-related change in routine (no intervention), which resulted in improved bladder storage outcomes (increased bladder capacity and compliance and reduced detrusor pressure) at the post-training time point. Even though scES parameters were not targeted to the urinary system and scES was not "on" during bladder testing, long-term gains in bladder capacity persisted a year after training (Herrity et al., 2020), indicating the existence of integrated locomotor and autonomic networks.

When stimulation was targeted for bladder function, key parameters were identified through scES configuration mapping at the caudal end of the array that improved reflexive voiding efficiency in a participant characterized with motor complete SCI (Herrity, Williams, Angeli, Harkema, & Hubscher, 2018). This configuration was also re-tested in four additional individuals (3 AIS A, 1 AIS B), improving bladder emptying in each one, using the same frequency found effective in the initial participant. In these examples, it is possible that sufficient excitation of the lumbosacral circuitry through scES can enable activation of both autonomic and motor spinal cord circuits that control the lower urinary tract, permitting timed detrusor contraction with adequate relaxation of the sphincters and pelvic floor to facilitate more efficient emptying. One important advantage of scES is its capability to simultaneously target multiple systems. Given the heterogeneous nature of neurogenic lower urinary tract dysfunction, it is likely that parameters may vary from participant to participant and configurations found effective for bladder storage may differ from those that improve bladder emptying. Use of multi-electrode scES arrays has the advantage of targeting cardiovascular-specific parameters to control blood pressure in response to bladder distention in susceptible individuals (those with injuries above T6) (Fig. 5), in addition to other patient-specific urological needs (i.e., those using indwelling suprapubic catheters vs. those performing intermittent catheterization).

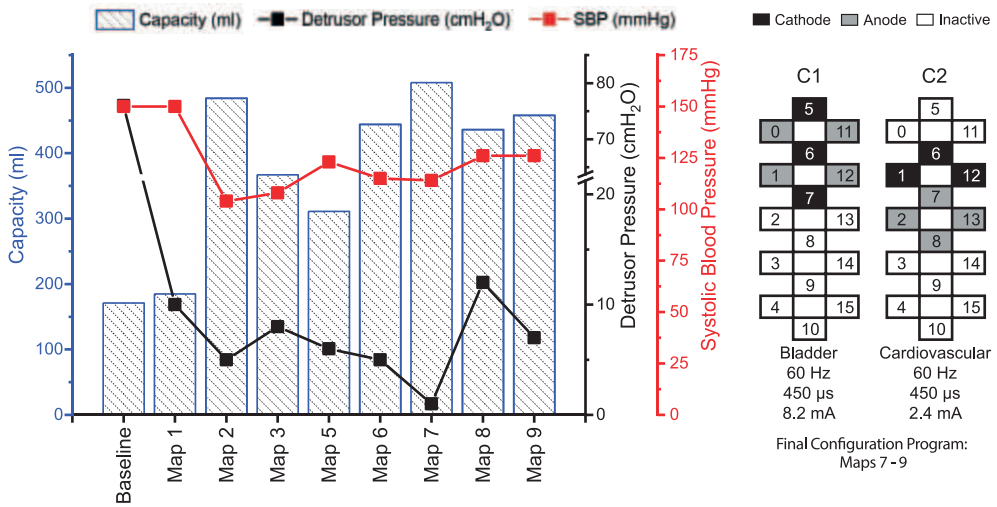

FIG. 5 Inter-system scES improves bladder function. Bladder mapping was conducted during urodynamics to identify specific stimulation parameters effective for bladder storage, which included maintaining bladder capacity *(blue)* within normative ranges established by the International Continence Society (300–600 mL) and maximum detrusor pressure < 40 cmH_2O *(black line)* (C1, cohort 1). Note the integration of a second cohort (C2), used to stabilize blood pressure *(red line)* in response to bladder filling.

Neuromodulation to improve bowel function

It has been demonstrated that electrical neuromodulation of gastrointestinal and autonomic networks can increase peristaltic activity to improve bowel motility and reduce constipation using a wide range of approaches including sacral nerve stimulation and wireless implanted stimulators within the GI system (Deng et al., 2018; Schiano Di Visconte et al., 2019). Vagal nerve stimulation of autonomic networks has also been shown to increase peristaltic activity and reduce inflammation in patients with inflammatory bowel disorders (Frøkjaer et al., 2016). Experimental pre-clinical studies evaluating the use of scES have demonstrated a role in reducing hypersensitivity associated with irritable bowel syndrome (Greenwood-Van Meerveld, Johnson, Foreman, & Linderoth, 2005) and modulating peristaltic activity in a rodent model of SCI (Hoey et al., 2021). In clinical studies with the Finetech-Brindley device, while stimulation of sacral anterior roots increased peristaltic activity in the distal colon and rectum, it also caused concomitant external anal sphincter contraction which prevented emptying during stimulation (Varma, Binnie, Smith, Creasey, & Edmond, 1986). Sacral nerve stimulation has primarily shown benefits in decreasing symptoms of constipation associated with neurogenic bowel dysfunction and decreasing episodes of incontinence in incomplete SCI (Lombardi & Del Popolo, 2009). In patients with gastroparesis, who have symptoms and pathophysiologic similarities to those with SCI (constipation, delayed emptying, prolonged transit time, autonomic dysfunction, abnormal inflammation, dysbiosis, metabolic abnormalities), direct gastric electrical stimulation improved symptoms of nausea and vomiting, constipation, decreased inflammation, and improved gastric motility (Abell et al., 2019). Compared to a conventional bowel routine, a 55%-fold reduction in bowel management time and a reduction in the neurogenic bowel dysfunction score from 15 (severe) to 8 (minor) was demonstrated using scES (preprogrammed for lower extremity and trunk activation) in a case report of one individual with motor complete SCI (Walter, Lee, Kavanagh, Phillips, & Krassioukov, 2018). A reduction in the time required to complete one's bowel program in one participant following the use of scES targeted for voluntary movement was also reported (Darrow et al., 2019). Despite these improvements, much remains unknown about the potential of and how best to target scES to improve bowel function after SCI. Further development of the parameters of stimulation and programming strategies for specifically targeting motility, maintaining continence and promoting evacuation are needed. Importantly, bowel distention is another main trigger of AD after SCI, and therefore, it is likely that stimulation will need to consider parameters to control blood pressure (similar to bladder) when scES is used to promote emptying during one's bowel program.

Neuromodulation to improve cardiovascular function

Cardiovascular autonomic regulation is also a complex interplay of sympathetic and parasympathetic stimulation which is mediated by the spinal cord as the key integrator of complex signals including baroreceptors from the periphery and from supraspinal centers in the brainstem. In spinally intact individuals, lumbosacral scES can promote increased peripheral blood flow in those with peripheral vascular disease (Huber, Vaglienti, & Huber, 2000) and increase blood pressure in a model of central baroreflex failure (Yamasaki et al., 2006). Early evidence of the benefit of spinal stimulation for cardiovascular function in SCI is demonstrated in a study examining the use of percutaneous epidural stimulation to reduce spasticity in 5 subjects, which subsequently resolved AD in four of five individuals (Richardson, Cerullo, & Meyer, 1979). Our recent work has demonstrated that scES in the absence of descending input can modify the excitability of relevant spinal interneuron pools allowing them to respond to peripheral autonomic input and approximate normal cardiovascular control (Harkema et al., 2018). In the context of human locomotor studies in SCI, scES used to facilitate motor activity in individuals undergoing stand training also increased arterial blood pressure, mitigating orthostatic intolerance and stabilizing blood pressure for the duration of standing (Aslan et al., 2018). By stimulating the lumbosacral spinal cord with individual-specific cardiovascular scES configurations, blood pressure can be effectively and safely elevated and maintained within normative ranges from a chronic hypotensive state, without activation of lower limb skeletal muscles, in individuals with severe SCI (Harkema et al., 2018; Legg Ditterline et al., 2020; West et al., 2018). Daily training with scES parameters for cardiovascular function has also been shown to acutely alleviate orthostatic hypotension during orthostatic stress testing, demonstrating an immediate cardiovascular responsiveness to scES (Harkema, Legg Ditterline, et al., 2018).

Future directions with scES and applications to other areas of neuroscience

Restoration of standing and stepping function as well as the regulation of autonomic function in chronic motor complete SCI has been achieved using the existing scES technology. However, the technology remains limited for full independent use in the home and community. The scES devices that are already FDA-approved (for use in chronic pain in non-SCI individuals), and IDE-approved for SCI, are not specifically designed to meet the complex needs

of the SCI population. Upgrading the stimulator's programming and wireless communication platforms to generate a more seamless system capable of delivering multiple training paradigms across multiple physiological systems is needed. The current gap that places the burden on the user to adjust and monitor stimulation and physiological parameters remains one of the most important limiting factors in the effective utilization of this technology outside the laboratory. Thus, to improve long-term adaptations and recovery of autonomic function, integrating use of the technology in the natural environment is key.

From a clinical perspective, identifying those individuals who will potentially benefit from scES, including those with other neurological disorders such as multiple sclerosis (Abbate, Cook, & Atallah, 1977), as well as establishing clear guidelines and protocols regarding the optimization and long-term adjustments of stimulation paradigms, have also been identified as critical areas to advancing the technology (Solinsky, Specker-Sullivan, & Wexler, 2020). Also, given the invasive nature of the scES approach, use of transcutaneous stimulation may be effective in identifying those individuals who respond to scES should device implantation be a future option, as well as testing and determining the optimal spinal locations for different autonomic functions. For example, pilot studies with transcutaneous stimulation applied over interspinous segments of T11 and L1 during urodynamics indicate improvements in bladder storage and emptying in individuals with motor/sensory complete through motor incomplete SCI (Gad et al., 2018; Kreydin et al., 2020).

Mini-dictionary of terms

- **Autonomic Dysreflexia (AD)**: A potentially dangerous syndrome that develops in individuals with cervical or upper thoracic spinal cord injury, resulting in acute, uncontrolled hypertension. AD is typically triggered by noxious or non-noxious peripheral or visceral stimulation below the level of SCI. The most common triggers of AD are from bladder and/or bowel distention.
- **Baroreflex:** a homeostatic response mechanism in which an elevation in blood pressure reflexively causes the heart rate to decrease and blood pressure to decrease.
- **Bowel program**: a regularly scheduled time dedicated to bowel emptying. The process usually begins with stimulating the anorectal region, typically using a suppository, enema, or by digital stimulation.
- **Detrusor-sphincter dyssynergia:** term used to describe a detrusor (bladder muscle) contraction with concomitant involuntary urethral sphincter activation, visualized during urodynamics, and typically present in individuals with neurologically induced bladder dysfunction.
- **Detrusor hyperreflexia:** characterized by the presence of involuntary uninhibited involuntary detrusor contractions, resulting in symptoms of urgency, frequency, and oftentimes, incontinence.
- **Gastroparesis:** impaired breakdown of food in the stomach and slowed gastric emptying resulting in primary symptoms of nausea, vomiting, and abdominal pain.
- **Hydronephrosis:** a condition characterized by excess fluid in a kidney due to the backup of urine, which can cause the kidney to swell.
- **Spinal cord epidural stimulation:** a neurostimulation device that delivers electrical signals through a lead implanted in the epidural space.
- **Urodynamics:** is an assessment of lower urinary tract function to objectively measure, explain and categorize how well the bladder, sphincters, and urethra are storing and releasing urine.
- **Vesico-ureteral reflux**: abnormal retrograde flow (reflux) of urine from the bladder up through one or more of the ureters and sometimes reaching the kidney.

Key facts of autonomic dysfunction after SCI

- Regulation of autonomic function requires an intact neural axis between supraspinal centers and spinal cord autonomic pre-ganglionic neurons.
- Disruption in autonomic nervous system control after SCI results in multi-organ system dysfunction and a loss of overall bodily homeostasis.
- The recovery of bladder and bowel dysfunction may be challenged by interactions from the cardiovascular system, especially in individuals with higher level injuries (above T6) experiencing multiple episodes of AD.
- Autonomic dysfunction has a major impact on the health, well-being, and quality of life in individuals with SCI.

Key facts of scES after SCI

- While initially focused on the motor system, the application of scES in motor complete SCI has more recently been shown to result in meaningful clinical improvements in autonomic function.
- The process of examining scES effects on bladder, bowel, and cardiovascular function begins with identifying specific stimulation parameters (location, rate, intensity, pulse width) during functional mapping that produce the desired outcome.
- Optimal improvements in autonomic function may necessitate the use of inter-system stimulation approaches in which an integration of configurations for multiple systems will enhance coordinated control (i.e., bladder storage and voiding with cardiovascular regulation).

Summary points

- This chapter discusses the widespread impact of SCI on autonomic function and how scES can be used to enhance recovery of bladder, bowel, and cardiovascular function.
- Autonomic dysfunction negatively impacts heath, well-being, and overall quality of life in individuals with SCI.
- Initial applications of scES in the SCI population focused on treating severe spasticity, which subsequently led to the examination of whether scES had the capacity to drive locomotor capabilities through excitation of the lumbosacral motor circuitry.
- Numerous pre-clinical and human studies have demonstrated that scES can also be used to drive meaningful gains in bladder, bowel, and cardiovascular function after SCI.
- Activity-dependent recovery training in combination with scES can facilitate functional reorganization of lumbosacral networks, strengthening residual connections between supraspinal axons and the spinal circuitry involved in autonomic regulation.

Abbreviations

AIS	American Spinal Injury Association Impairment Scale
CRPS	complex regional pain syndrome
EES	epidural electrical stimulation
EMG	electromyography
FBSS	failed back surgery syndrome
IPG	implantable pulse generator
MRI	magnetic resonance imaging
SCI	spinal cord injury
SCS	spinal cord stimulation
SCSr	spinal cord stimulator

Introduction

Spinal cord injury

Spinal cord injury (SCI), which literally means damage to the spinal cord, is a devastating and debilitating neurological condition, affecting millions of people worldwide. Traumatic SCI caused by external impacts accounts for the majority of all SCI cases and always accompanies a secondary injury that causes the further death of neurons and glial cells, leading to long-term neurological defects and paralysis. It can significantly harm the spinal cord's functions and burden patients, their families, and friends with substantial personal and socio-economic pressures. According to the 2020 SCI datasheet reported by the National Spinal Cord Injury Statistical Center, approximately 294,000 persons are living with SCI in the United States, with about 17,810 new cases every year, while the World Health Organization (WHO) had estimated that 250,000–500,000 people suffer an SCI each year around the world (Alam et al., 2020; Courtine & Sofroniew, 2019). Clearly, SCI has caused a significant burden on the healthcare system all over the globe.

Etiologically, SCI can be categorized into two types: traumatic SCI and non-traumatic SCI. Traumatic SCI is caused by external physical impacts such as vehicle accidents, sports injuries, violence, or falls. In a traumatic SCI, the external impact firstly causes bone, blood vessel, and ligament damage of the spine, then the debris and dislocation subsequently hurt and rip the spinal cord tissue, initiating the primary injury. After that, it leads to a secondary injury cascade (Fig. 1), resulting in the death of glial cells and neurons, and a long-term neurological defect (Ahuja et al., 2017). Differently, non-traumatic SCI is usually caused by other chronic or degenerative disorders such as tumors or infection, which however can induce a similar level of neurological deficit to a traumatic one. Despite its existence, non-traumatic SCI rarely happens compared with the traumatic SCI that accounts for over 90% of all SCI cases (Alizadeh, Dyck, & Karimi-Abdolrezaee, 2019).

With the improvement in emergency healthcare and medical services, many patients can survive from traumatic SCI and usually live up to a very optimistic life expectancy, however, frequently accompanied by terribly devastating disabilities. The injury cascade leads to complications such as inflammation, ischemia, and subsequently ruin in organization and structure of the spinal cord. Indeed, the clinical outcome is also heavily subject to the location and severity of the injury, since the patients may be partially or wholly paralyzed—depending on the lesion intensity—lose the sensory and motor functions below the level of the lesion, resulting in different extents of disability such as paraplegia and quadriplegia. If the

Diagnosis and Treatment of Spinal Cord Injury. https://doi.org/10.1016/B978-0-12-822498-4.00019-1

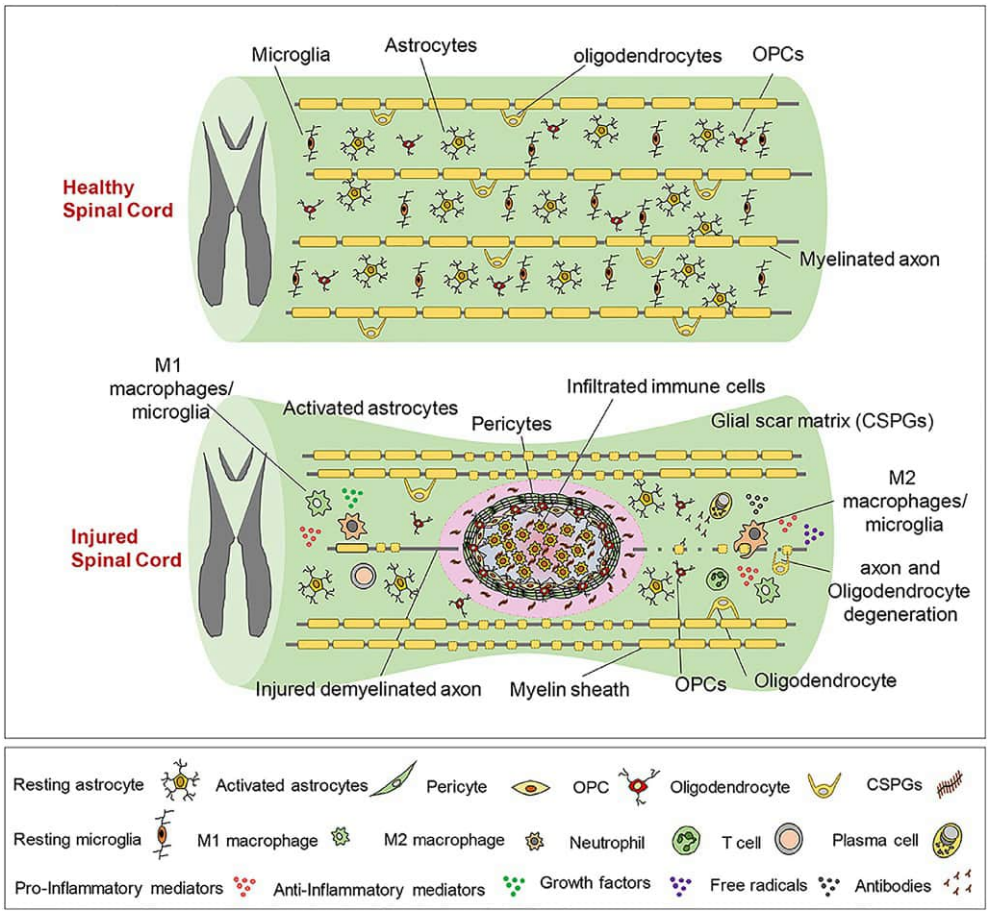

FIG. 1 Pathophysiology of traumatic spinal cord injury. In the healthy spinal cord, axons remain intact, are supported and protected by glia, astrocytes, or other components. After traumatic SCI, a secondary injury following the primary injury leads to the death of glial cells and neurons, initiating a series of devastating responses leading to motor and sensory function loss. *(Reprinted with permission from Alizadeh, A., Dyck, S. M., & Karimi-Abdolrezaee, S. (2019). Traumatic spinal cord injury: An overview of pathophysiology, models and acute injury mechanisms [review]. Frontiers in Neurology, 10(282). https://doi.org/10.3389/fneur.2019.00282.)*

sensory and motor function is totally lost below the injury level, it is clinically defined as a complete SCI; but if there is still any spare function left, it is called an incomplete SCI (Gaber & Brown, 2020). Regardless of different levels of disability, the loss of independence and ability returning to a job and daily life causes immense difficulties, extra works, and costs in caring for SCI patient's daily living. The lifetime cost for each SCI patient is estimated to be US$2.35 million (Alizadeh et al., 2019), which is definitely a considerable amount for many families, especially under the circumstance that the patient themselves cannot often work in their regular jobs anymore. Besides the loss of sensorimotor functions, chronic pain is another common problem, which frequently happens after SCI, with a rate of about 30%–80% and strikingly one third of which suffer from severe pain (Dijkers, Bryce, & Zanca, 2009; Widerström-Noga et al., 2008). Consequently, understanding SCI's pathophysiological mechanism and developing effective treatment to this condition is critical and highly significant.

Treatments for SCI

Over the years, although substantial research and efforts have been contributed to study the SCI, there is still no known method to reverse or cure the damage of SCI at present. Fortunately, different strategies have been found to improve the lost sensorimotor functions, self-independence, and life quality of SCI patients; and other promising treatments are also in progress. Currently, available treatments for SCI are mainly in three aspects: intervention shortly after the injury happens (acute stage), compensatory strategies, and functional recovery in sub-acute and chronic stages (Roy, Harkema, & Edgerton, 2012). The primary purpose of interventions after acute SCI is to decompress the spinal cord and minimize

secondary injury. The typical early intervention approach includes surgical and pharmacological interventions. Though applications on animal models had suggested beneficial outcomes of surgical interventions, its effect on human trials remains unclear (Silva, Sousa, Reis, & Salgado, 2014). Also, despite some successful cases, the ability of pharmacological interventions to improve neurological function remains controversial at present and requires more demonstrations in patients (del Popolo, Mencarini, Nelli, & Lazzeri, 2012). The compensatory strategies usually help improve functions by utilizing assistive devices or training modalities to shift the tasks to unaffected body parts. Compensatory strategies are commonly employed to complete SCI, which has relatively limited restoring capability of the spinal cord functions (Alam & He, 2014; Alam & Zheng, 2017). On the other hand, functional recovery strategies attempt to restore the functions after SCI by means such as stimulations or neurorehabilitation training. These strategies normally show better outcomes for less severe SCI since incomplete SCI has a higher chance of functional recovery; however, stimulation-induced motor function recovery after complete SCI is also heavily investigated (Dietz & Fouad, 2014; Gaber & Brown, 2020). A promising rehabilitative strategy to SCI in recent years is spinal cord stimulation (SCS), which has shown encouraging outcomes in not only functional recovery but also SCI pain relief even in patients who did not expect to improve any function with classical interventions (James, McMahon, Field-Fote, & Bradbury, 2018). In this chapter, we have discussed the principles behind the SCS-mediated rehabilitation of sensorimotor functions after SCI, introduced several notable spinal cord stimulators, and illustrated the procedures of their clinical application.

Spinal cord stimulation

Principles of SCS

SCS has been used to treat neuropathic pains for over 50 years. It is often applied to alleviate chronic pain for which conventional treatments have failed, such as congenital or acquired chronic low back and leg pains, complex regional pain syndrome (CRPS), failed back surgery syndrome (FBSS), and post-SCI pains, etc. (Giugno et al., 2017). SCS blocks pain but not cures it. SCS relieves pain by generating electric pulses at the spinal cord. Its working principle to block pain is the gate control theory of pain (Fig. 2). Gate control theory indicates that other inputs will shut the "nerve gate" for the painful input in the spinal cord, preventing pain signals from reaching the brain so that one does not feel the pain (Ireland, 2010). Based on this theory, the stimulator produces electrical pulses on the spinal cord's dorsal surface, which closes the "nerve gate" to pain signals, prevents them from being received by the brain, thus masks the neuropathic pains (Mammis, 2016).

Besides, SCS starts to serve as a promising tool for movement restoration after SCI. Both invasive and non-invasive SCS could be a powerful tool. The exact principle underlying the motor function improvement by SCS is largely unknown at present. Some findings suggest that even isolated from the brain the spinal circuitry is still able to generate locomotor activity driven by the externally applied stimulation (Courtine et al., 2009; Dimitrijevic, Gerasimenko, & Pinter, 1998; Shah et al., 2016). According to this principle, the SCS replaces the brain to generate stimuli for triggering locomotor-like activity for the paralyzed. So SCS with different patterns, amplitudes, frequencies, pulse widths at different locations may result in different locomotor activities. Theoretically, these motion activities could happen only if SCS is applied to the patient sustainedly. However, another explanation suggests that instead of replacing the brain, the SCS enables the brain

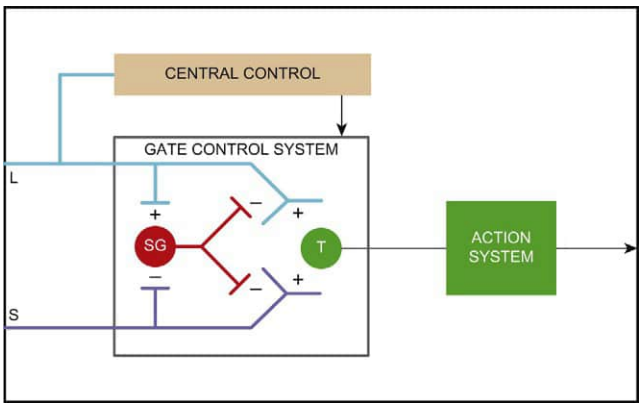

FIG. 2 The gate control theory of pain. The inhibitory neurons in substantia gelatinosa (SG, lamina II) are excited by the non-nociceptive input (L) and thus close the pain gate. *(Reprinted with permission from Braz, J., Solorzano, C., Wang, X., & Basbaum, A. I. (2014). Transmitting pain and itch messages: A contemporary view of the spinal cord circuits that generate gate control. Neuron, 82(3), 522–536. https://doi.org/10.1016/j.neuron.2014.01.018.)*

to recruit the spared and functionally silent nerves residue in SCI, so the reorganization of the residual neural pathway by the SCS promotes and improves locomotor functions (van den Brand et al., 2012). In this theory, the brain is still the command center of the limb movement, and the role of SCS is just to activate the residual neural pathway important for locomotion. So, it is possible that after a period of SCS, the locomotor improvement became long-term and sustained even after the SCS is removed.

Functional rehabilitation with SCS

Though the detailed mechanisms remain largely unclear, many studies found that SCS has benefits on motor function recovery after incomplete or complete SCI, notably in patients' voluntary movement, standing, and stepping recovery as well as cardiovascular and bowel functions management (Table 1). Harkema et al. (2011) propose that tonic SCS could modulate spinal cord circuitry and enable patients with paralysis after SCI to undertake tasks such as standing and stepping. They reported a case in 2011 that a paraplegic patient was able to undergo a full-weight bearing standing and some leg movements during task-specific SCS (Harkema et al., 2011). The subject in the study had a clinically complete loss of voluntary motor function but incomplete sensory SCI, so the regain of some voluntary functions in this study is interpreted by that the residual but silent neuropathway was reactivated or the neuroplasticity was promoted by the SCS (Edgerton & Harkema, 2011). However, in a later study reported in 2014, they found that even for the patients diagnosed with a complete motor and sensory SCI, SCS can still help to proceed detectable leg movements after the paralysis for years (Angeli et al., 2014). This finding uncovers that SCS could be a potential rehabilitative tool for diagnostically complete SCI even a long time after the injury happens. These previous studies apply a relatively low stimulation frequency—usually below 30 Hz—for SCS, and patients still need some external assistance to stand. In 2015, they also reported that two motor-complete but sensory-incomplete SCI patients were able to process full-body weight standing without using any external assistance (Rejc et al., 2015). In this study, a higher stimulation frequency (25–60 Hz) relative to that in previous studies (<30 Hz) lends to an EMG pattern more effective for patients to stand. Also, a body weight-bearing sensory input could remarkably increase the EMG activity to sufficient for standing, while very little EMG activity was generated by lower limb muscles during epidural SCS. The research by Sayenko et al. also demonstrated that the stimulation parameters and sensory conditions significantly influence the SCS outcomes, showing different stimulation responses between standing and supination (Sayenko, Angeli, Harkema, Edgerton, & Gerasimenko, 2014). Besides lower limb movement recovery, SCS at the cervical level was also successfully applied to improve upper limb motor functions and promote voluntary hand movements for patients with tetraplegia (Lu et al., 2016; Qian, Ling, Zhong, Zheng, & Alam, 2020).

In the studies mentioned earlier, the efficacy of SCS on SCI motor function recovery has been witnessed; nonetheless, volitional movements were generated only if real-time task-specific SCS is being provided. Rejc et al. (2017) had progressively found the reemergence of muscle activation pattern sufficient for the standing of complete SCI patients without any real-time SCS after they underwent long-term task-specific motor training with SCS (Rejc et al., 2017). After then, a number of recent studies also showed that a period of SCS motor training enabled SCI patients to conduct independent standing and stepping over the ground (Angeli et al., 2018; Gill et al., 2018; Wagner et al., 2018). These achievements reveal that SCS could stimulate real-time motor activation and be a promising training tool to recover the independent motor functions for patients with complete chronic SCI (Fig. 3) (Cho, Squair, Bloch, & Courtine, 2019).

Spinal cord stimulators

Current spinal cord stimulators

There are currently various kinds of spinal cord stimulators on the market. This section briefly discussed several typical products and compared their properties and features (Table 2). Precision Spectra is an SCSr designed by Boston Scientific Corporation. Its function mainly focuses on pain relief. This product's working principle is similar to what was mentioned previously: generating impulses to mask the pain signals before they could reach the brain. Precision Spectra is featured with more coverage, high flexibility, and advanced control. It is a safe, drug-free, approved by the Food and Drug Administration (FDA) of the United States, and paresthesia-free pain management therapy that is clinically proven to help reduce chronic pains. The Spectra can be personalized for every individual's unique pain and can deliver more than one type of stimulation simultaneously, even at multiple areas, to find the optimum treatment for a particular pain. Firstly, Spectra introduces the world's first implantable pulse generator (IPG) with 32 contacts and a dedicated power source, providing more excellent coverage and more precise targeting to the spinal cord but not increasing the product size. Secondly, Spectra presents an unprecedented level of flexibility. The combination of the four-port design and the broad lead portfolio enables

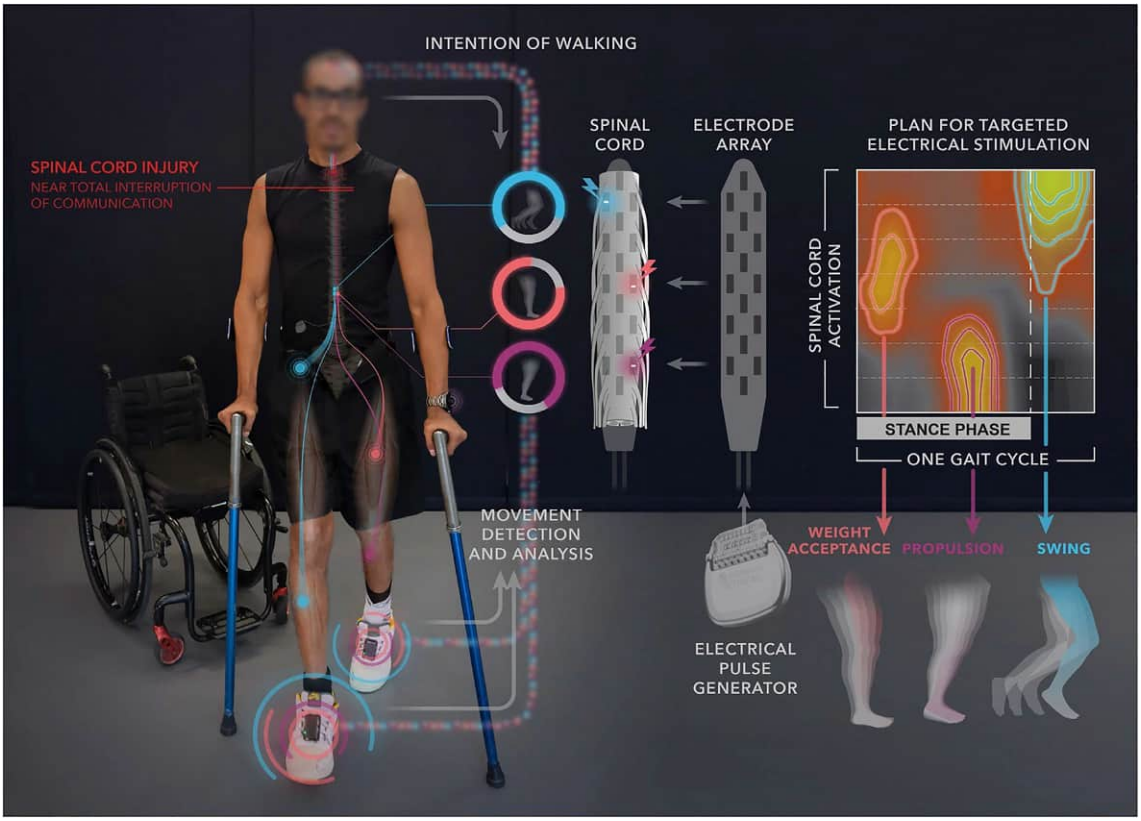

FIG. 3 Enabling over-ground walking with SCS in SCI patients. Stimulation bursts matching the spatial and temporal dynamics of the neural network reproduces natural activation of the spinal cord and enables locomotion in SCI. The spinal cord activation map was reconstructed based on the projection of electromyographic signals on an estimated location of the neural circuit in the spinal cord. *(Reprinted with permission from Cho, N., Squair, J. W., Bloch, J., & Courtine, G. (2019). Neurorestorative interventions involving bioelectronic implants after spinal cord injury. Bioelectronic Medicine, 5(1), 10. https://doi.org/10.1186/s42234-019-0027-x.)*

unmatched flexibility of lead configuration to adapt the possible change of the pain patterns in the future. Besides, Spectra also provides a series of advanced control technologies.

Proclaim XR is a recharge-free SCS system developed by Abbott Laboratories. A long-lasting battery of up to 10 years is a highlight in this SCSr. The battery longevity without any recharging is achieved by delivering low-dose stimulation. Proclaim XR applies BurstDR stimulation therapy, also known as burst stimulation, which imitates natural firing patterns of the human central nervous system to have better pain relief than tonic stimulation and potential benefits to various mechanisms of action (Kirketeig, Schultheis, Zuidema, Hunter, & Deer, 2019). BoldXR dosing protocol is used for patient-specific stimulation to ensure the optimal dose to have the best outcome and prevent the side effects of over-stimulation.

Restore by Medtronic is a family of FDA-approved SCSr that allows the patients to have an MRI scan. There are three IPGs with little differences under this series. Restoresensor Surescan stimulator features a customized pain management pattern and an automatic adjustment between low and high doses to achieve the optimal stimulation setting at the proper position. Restoreadvanced Surescan MRI stimulator specifically features the longest battery endurance among all Medtronic stimulators through a low dose programming. RestoreUltra SureScan allows safe access to the MRI scan, which is FDA-approved for 1.5-Tesla anywhere on the patient's body.

Omnia is a next-generation SCSr launched by Nevro Corporation. The selling point of Omnia is maximum versatility, able to deliver and combine all approved frequencies from 2 to 10,000 Hz, and claimed to have the broadest range of stimulation solution. It provides both direct neural pain inhabitation with a 10 kHz—high frequency (HF10) therapy and dorsal column stimulation at traditionally low frequency; or it can even pair high frequency with low frequency, HF10 with a burst to generate various blending waveforms for different individuals. Also, Omnia is claimed to have the fastest charging rate in SCSrs and is labeled with a full-body conditional MRI scan.

Four common commercial SCSrs and their basic information: Precision Spectra by Boston Scientific; Proclaim XR by Abbott Laboratories; Restoresensor Surescan MRI by Medtronic; and Omnia by Nevro.

Surgical implantation of neurostimulators

For chronic use, an SCSr is needed to be implanted into the body, which is an invasive procedure that commonly requires surgery. Hence, SCS usually requires candidate evaluation before implantation. Usually, a patient receiving more than 50% pain relief in the trial with all other criteria reached is regarded as a suitable candidate; otherwise, they are not good candidates for the stimulator implantation (Mammis, 2016). In this section, different components of SCSr implantation procedures are introduced.

As mentioned in the previous section, an SCSr commonly have three main components: the leads, an implantable pulse generator (IPG), and an external wireless programmer (Fig. 4). There are also three main types of pulse generators: the conventional one requires another surgery to replace the battery once it runs out, the rechargeable one with a battery that can be recharged without any surgery, and the radiofrequency one with a battery outside the body.

In the trial stimulation, the injection site is first given a local anesthetic. Then insulated leads are inserted through a needle into the epidural space of the spinal cord, guided by fluoroscopy. The electrodes on the lead terminal are then

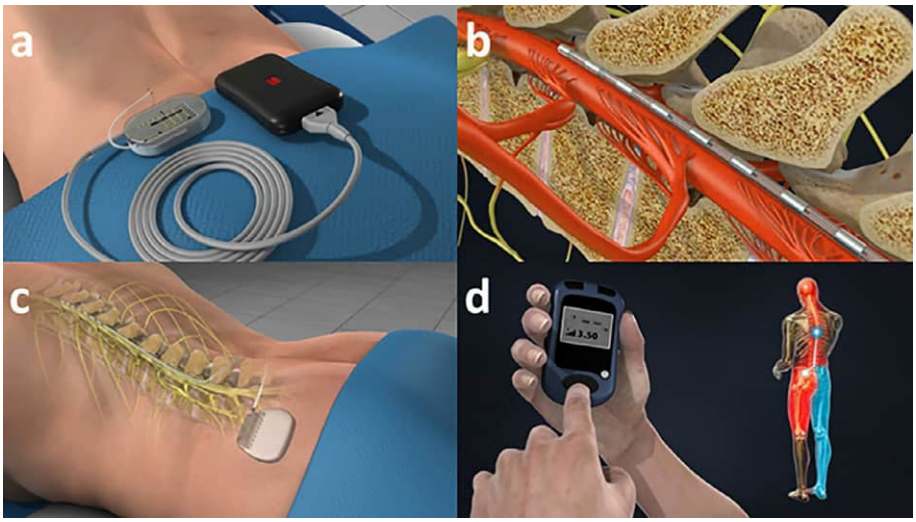

FIG. 4 Surgical steps of a spinal cord stimulation system. (A) Trial stimulation with a temporary SCSr. (B) Insertion of the lead electrodes into the epidural space. (C) Implantation of the IPG at the buttock. (D) Using a wireless programmer for operating the stimulator. *(Printed with permission from ViewMedica.)*

intermittently activated to generate electrical impulses to block the pain signals. During this procedure, the patient gives feedback to help the physician determine the best placement of the electrodes. The lead is then linked to an external trial stimulator for a trial lasting for about 1 week to evaluate SCS efficacy. If the SCS shows an acceptable result during the trial period, permanent implantation may be conducted. The trial leads are removed, and similarly, the patient is anesthetized, and the permanent leads are inserted into the epidural space. A small incision is then created, and the implantable pulses generator (IPG) is implanted in the buttocks. The leads are connected to the IPG. Finally, the external programmer can be used to turn on or off the generator and adjust the stimulation power level and other settings.

Significance of SCS

Motor function deficit and chronic back and leg pain remain critical problems in spinal disorders, affecting millions of patients worldwide. They severely affect patients' self-independences and life qualities, yet traditional medical treatments such as pharmaceutical and surgical interventions often fail to achieve satisfactory results. In contrast, SCS shows significant performance in treating neuropathic pains for which conservative treatments have failed and promising efficacy on motor function improvement after clinically complete or incomplete SCI. The application of SCS on pain relief has been relatively mature, with many studies proving its effectiveness and various kinds of products available on the market. Furthermore, as the functional mechanism is well understood, emerging stimulations with different frequencies, waveforms, and patterns are used to achieve user-specific and more effective therapies.

SCS also demonstrates its significance in motor function restoration. In previous studies, SCS has been used to improve animal models and humans' motor function after an SCI (Wenger et al., 2016). The paraplegic patients were able to conduct voluntary leg movements such as standing, stepping over the ground, or bladder control via SCS. Closed-loop neurostimulation has also shown promises for optimal micturition for SCI (Peh et al., 2018). Sufficient muscle activities related to these motions could be measured during the SCS. Furthermore, after a period of task-specific training with SCS, the patients presented an improvement in standing and stepping independently, even when the SCS was removed. This indicates that the motor function restoration can persist beyond the SCS period. Neuroplasticity plays a significant role in these permanent recoveries (Alam, Rodrigues, Pham, & Thakor, 2016; Ling, Alam, & Zheng, 2019). Based on breakthroughs in the existed studies, SCS is promising to be developed into effective tools for functional restoration following SCI, as the functional mechanism behind them is currently being investigated more deeply.

Current limitations of the neurostimulators

There has already been a wide variety of SCSrs available on the market at present. As mentioned in the previous section, companies such as Boston Scientific, Abbott Laboratories, Medtronic, and Nevro have offered their own SCSr with unique features. These stimulators present various characteristics, such as large pain coverage, long-lasting battery, MRI

compatibility, flexible therapy, etc. However, the current stimulators still have some limitations (Alam et al., 2019; Li et al., 2020). One of them is the invasiveness of the stimulator implantation via surgery, implicating the risks of bleeding, allergic response, infection, etc. The trial stimulations indicate extra implantation; meanwhile, the change of patient's pain condition needs stimulation adjustment and might require additional surgeries for new stimulator implantations, especially for those stimulators unable to provide designable stimulation patterns. Another problem is the device-related problem such as lead migration, connection failure, or damage during use.

A more critical problem of all existed stimulators on the market is their application scope, designing purposely for pain relief. It means that the stimulation pattern, frequency, or waveform of the stimulators are not designed for functional restoration. Hence, SCSrs' application in SCI patients is mostly limited since the pain relief is more likely the emphasis in treating SCI compared with the restoration of function.

Advanced neurostimulators

Besides the current SCSr mentioned above, a recently developed injectable stimulator developed by Stimwave Technologies, Freedom-8A, is a futuristic SCS system, which may overcome some limitations of the existed SCSrs (Billet, Wynendaele, & Vanquathem, 2018). Unlike traditional stimulators requiring bulky implantation, Freedom-8A is a wireless system with only one micro-size component to inject into the epidural space. Without a battery and wires accompanied, Freedom-8A is much smaller and does not require an IPG, which makes it less invasive and reduces the implants' paresthesia. Meanwhile, Freedom-8A can provide up to 64 electrode contacts, twofold of Precision Spectra mentioned previously, and 3.0 T full-body MRI compatibility. It also provides programmable stimulation with a frequency of up to 10 kHz. By integrating features of existed stimulators with its own novelties, Freedom-8A is offering a minimally invasive all-in-one SCS solution for SCI patients. A large clinical outcome of this stimulator is, however, yet to be reported.

GTX Medical, a newly founded spin-off from the Swiss federal institute of technology Lausanne (EPFL), is developing a new generation SCSr for targeted epidural SCS therapy to promote recovery of motor functions and neurologic control in adults with SCI and paralysis based on the recent research findings (Wagner et al., 2018). Their implantable Go-2 system, which is designed to deliver targeted epidural SCS therapy, has recently (June 2020) granted United States Food and Drug Administration (FDA) breakthrough device designation. The Company anticipates the first clinical trial for the complete Go-2 system in patients to take place in 2021.

Prospects of the stimulation for spinal cord injury rehabilitation

A non-invasive SCS could be the solution to the problems that arise from the invasiveness of the SCSrs. Some studies found that besides the epidural SCS, transcutaneous SCS, which is non-invasive without requiring any surgeries, could also enable mobility after SCI and may confer similar outcomes to epidural SCS if suitable parameters are adopted (Gerasimenko, Kozlovskaya, & Edgerton, 2016; Ievins & Moritz, 2017). If the non-invasive transcutaneous SCS could achieve comparable efficacy on motor function improvement to the epidural SCS and even replace it in the future, a great number of complications caused by surgery will be readily solved.

Until today, most commercially available SCSrs are working on pain relief when the application on motor function restoration after SCI is still at the experimental stage. Although many previous results have demonstrated the improvement of motor function for paralysis following SCI during the stimulation period, the preferable breakthrough in the future may be that the SCS training could achieve sustained and unrelenting motion improvement, which means after a period of training the patients could persist the mobility even beyond the period of stimulation (Ievins & Moritz, 2017). More investigations on the mechanism behind SCS induced functional improvement are needed to achieve this goal. Also, the efficacy of SCS on the recovery of more complex movements, such as dexterity control, continued walking, balance, requires further research study and clinical trial (García, Serrano-Muñoz, Taylor, Avendaño-Coy, & Gómez-Soriano, 2019). Lastly, combining SCS with pharmaceutic and cellular interventions may also lead to effective treatment to improve voluntary movement after SCI in the future.

Applications to other areas of neuroscience

In this chapter, we have reviewed the application of SCS by the SCSrs on improving motor functions and relieving chronic pain caused by SCI. We also discussed the advancements and limitations of the existing stimulators and then prospected on the futuristic stimulators in these processes.

The application of SCS also demonstrates high efficacy for pain relief in other neurological or spinal disorders, especially those that fail the conventional treatment approaches. These include failed back surgery syndrome (FBSS), complex regional pain syndrome (CRPS), others such as arachnoiditis, heart pain, nerve-related pain, peripheral vascular diseases, post-amputation pain, and visceral abdominal pain and perineal pain. Indeed, the sources of pain in the above disorders could be very different from the pain of the SCI. However, due to the nature of SCS pain relief, blocking the pain signals from reaching the brain by generating electric pulse, it is reasonable that SCS can be used for other chronic pain relief.

A recent study assessed a group of type I CRPS patients on pain relief and their life qualities after SCS implantation. The result shows that pain relief occurs in most subjects after SCS (Mammis, 2016). While another review on 80 cases of SCS treatments shows that at a 12 months follow-up, 40% of patients did not require medication anymore, while the rest claimed that the pain became manageable accompanied by using a first-line analgesic (Gopal, Fitzgerald, & McCrory, 2016). Similarly, various studies have shown evidence that SCS has clinical effectiveness on FBSS pain relief. One trial applies traditional SCS surgery, which is low-frequency SCS, for a group of subjects who have suffered from unrelenting post-spinal-surgery back pain for more than 3 months. The results collected over more than 2.5 years show about 50% pain relief for 50% of patients (Kumar et al., 2005; Kumar et al., 2007; North, Kidd, Farrokhi, & Piantadosi, 2005).

Mini-dictionary of terms

Spinal cord injury: The damage to the spinal cord. It is often caused by trauma, and the severe one can result in paralysis.
Neuromodulation: The alteration of nerve activity via a certain stimulus such as electrical stimulation, electromagnetic stimulation, and chemical agents.
Spinal cord stimulation: The use of electric impulses to stimulate the region of the spinal cord for a certain purpose. Spinal cord stimulation can be either invasive or non-invasive.
Spinal cord stimulator: The device that delivers spinal cord stimulation.
Complete SCI: The spinal cord injury causing the total loss of communication between the brain and nerves below the point of the injury. It implicates paralysis.
Incomplete SCI: The spinal cord injury in which there is still residual motor or sensory communication between the brain and nerves below the point of the injury. It implicates a paresis.
Neuropathway: The connection formed by axons to enable signals to be sent from one region to another in the nervous system.
Paresthesia: An abnormal sensation. The cause of paresthesia could be various.
Epidural space: The space between the dura mater and the vertebral wall, just above the dural sac.
Chronic pain: The pain lasting for over 3 months, usually coming and going without clearly know reasons.

Key facts of spinal cord injury

- Millions of patients are currently suffering from spinal cord injury (SCI) worldwide, and an estimated 768,473 new cases occur every year.
- There are mainly two types of SCI: traumatic and non-traumatic SCI, when over 90% are traumatic SCI.
- Primary and secondary injury cascades in traumatic SCI cause the death of neurons and glial cells, resulting in long-term neurological defects.
- SCI can cause disabilities: paraplegia and quadriplegia are commonly seen depending on the injury level, sometimes accompanied by pains.
- Complete SCI features the complete loss of sensory or motor functions below the injury site when incomplete SCI has limited function through the residual connection between the brain and nerves below the injury.

Summary points

- Spinal cord injury causes paralysis and chronic pain, affecting millions of patients' self-independence and life quality worldwide.
- Therapeutic and surgical interventions show limited efficacy in restoring patients' functions after SCI.
- Spinal cord stimulation presents a stunning performance in treating chronic back or leg pain and promising effectiveness in improving motor functions after SCI.
- In some studies, patients with motor complete SCI were able to conduct locomotor functions such as weight-bearing standing and stepping over the ground during SCS.

- There are various kinds of spinal cord stimulators on the market targeting chronic pain relief. These stimulators possess large pain coverage, flexible and customized therapy, high-frequency stimulation, and MRI compatibility to achieve a better outcome and user experience.
- There are few spinal cord stimulators specially designed for motor function improvement on the market yet. Further understanding of the mechanism behind SCS will be needed to develop safe and effective stimulators for improving motor functions for SCI.

DRS	digital rectal stimulation
EAS	external anal sphincter
ENS	enteric nervous system
LMN	lower motor neuron
NB	neurogenic bowel
SARS	sacral anterior root stimulation
SC	spinal cord
SCI	spinal cord injury
UMN	upper motor neuron

Introduction

Spinal cord injury (SCI) results in loss of motor, sensory and autonomic functions, causing dysfunction of practically all body systems leading to long-term complications (Table 1). Neurogenic bowel (NB) is one of these main impairments after spinal cord injury. It occurs because of changes in innervation of the colon and rectum, as well as the loss of voluntary control of the anal sphincter, affecting colonic motility and defecation maneuvers. Between 80% and 97% of people with SCI suffer at least one NB-related symptom (Correa & Rotter, 2000; Ozisler, Koklu, Ozel, & Unsal-Delialioglu, 2015), mostly constipation and/or fecal incontinence, but also a prolonged and difficult defecation, sense of incomplete emptying, abdominal pain and distension, autonomic dysreflexia (AD), hemorrhoids, and rectal prolapse. Twenty-seven percent of the subjects considers that bowel dysfunction is a greater problem than bladder or sexual dysfunction, and 38% perceive it limits their quality of life (QoL) or social activities (Faaborg, Christensen, Finnerup, Laurberg, & Krogh, 2008).

The level of injury, severity, and presence or absence of sacral reflexes influences NB clinical manifestations and its management. Constipation and incontinence tend to become chronic and are stubborn toward currently available treatments, being a relevant source of complications. This, and the amount of time people with spinal injury spend on their bowel care, causes neurogenic bowel dysfunction (NBD) to have a very negative effect on QoL.

Characteristics of neurogenic bowel in spinal cord injury

Nervous control of the colon is done through the enteric, autonomic, and central nervous systems (Chung & Emmanuel, 2006; Lynch, Antony, Dobbs, & Frizelle, 2001). The enteric nervous system (ENS) is key for generating colonic propulsive activity. It functions independently, but is modulated by the spinal cord (SC) through the sympathetic fibers arising in the intermediolateral column of T5 to L3 and parasympathetic fibers that originate in segments S2 to S4. Sympathetic fibers inhibit colon motility, while parasympathetic fibers enable the contraction of the left colon, sigmoid, and rectum. The motor neurons in S2–S4 innervate the external anal sphincter (EAS), the puborectalis muscle, and the muscles of the pelvic floor;

TABLE 1 Principal medical issues after spinal cord injury.

Respiratory complications[a] Atelectasis, pneumonia and respiratory failure
Cardiovascular complications[b] Orthostatic hypotension, autonomic dysreflexia, bradycardia
Neurogenic bladder
Neurogenic bowel
Sexual and fertility dysfunction
Spasticity[c]
Chronic pain Nociceptive pain Neuropathic pain: Above the level, at the level or below the level of injury
Secondary immunodeficiency[d] Increased susceptibility to infections
Osteoporosis Increased risk of low impact fractures
Neurogenic heterotopic ossification[e]
Pressure sores

[a]*Due to paralysis of the phrenic nerve, intercostal muscles and/or abdominal muscles leaving to reduced lung capacity and ineffective cough.*
[b]*Due to loss of supraspinal sympathetic control in patients with injury at T6 and above.*
[c]*Velocity-dependent increase in muscle tone with exaggerated deep tendon reflexes that results from injury to upper motor neurons.*
[d]*Systemic dysfunction of macrophages, T cells, B cells, and natural killer cells due to disruption of central nervous system input to immune organs.*
[e]*Ectopic bone formation in the connective tissue around joints.*

they receive voluntary control from motor neurons of the cerebral cortex and sensitive information from mechanoreceptors of the pelvic floor. SCI causes disturbances in autonomic and central innervation, and consequently loss of voluntary control of defecation, and changes in intestinal motility and sphincter tone. Various studies report a slowing of total and/or segmental colonic transit (Correa & Rotter, 2000; Vallès, Vidal, Clavé, & Mearin, 2006), increased colonic wall tone, changes in rectal compliance (Trivedi, Kumar, & Emmanuel, 2016) and in sphincter tone and sensitivity, as well as lack of relaxation of the anal sphincter in response to rectal distension (Lynch, Anthony, Dobbs, & Frizelle, 2000). Although the function of the ENS remains, it has been shown there is loss of neurons and decrease of nerve fiber density in the myenteric plexus (den Braber-Ymker, Lammens, van Putten, & Nagtegaal, 2017) after SCI. The inflammatory process and changes of extrinsic innervation may alter neuromuscular structures of the colon and contribute to decrease bowel function (White & Holmes, 2019). Not much research has been carried out on the changes of gut microbiota; however, it may well be a contributing factor and thus a target of study for the development of new treatments (Zhang et al., 2018).

Based on the level of SCI, two bowel dysfunction patterns may be distinguished. Lesions over the medullary cone cause upper motor neuron NB syndrome or *hyperreflexic bowel*, in which case there is loss of supraspinal control, but reflex coordination and stool propulsion are preserved. This syndrome is characterized by the increase in the tone of colonic and anal wall, the sphincter remains its tone or it becomes hypertonic, and spasticity of pelvic floor muscles may occur. It associates with constipation and fecal retention; incontinence due to overflow or reflex relaxation of the anal sphincter may also develop. Lesions in the medullary cone and cauda equina cause lower motor neuron NB syndrome or *areflexic bowel*, in which case there is loss of supraspinal control, reflex activity mediated by the spinal cord, and the sphincter is hypotonic. Colonic peristalsis occurs only because of the activity of the ENS, which results in an increase of colonic transit time (CTT). The areflexic bowel is associated to constipation, less difficulty during defecation, and high risk of incontinence due to EAS atony.

Clinical manifestations

Constipation, fecal incontinence, pain, and abdominal distension are the main symptoms of NB in people with SCI. *Constipation* is associated with slowing colonic transit, failure to increase intra-abdominal pressure during defecation, absence

of anal relaxation during the defecation, and increase of rectal and sigmoid compliance (Trivedi et al., 2016; Vallès & Mearin, 2009). Immobility and use of drugs such as opioids or anti-cholinergics, also favor constipation (Paily, Preziosi, Trivedi, & Emmanuel, 2019). Mean time for stool evacuation is longer, with 35% of SCI patients requiring more than an hour (Engkasan & Sudin, 2013; Inskip, Lucci, McGrath, Willms, & Claydon, 2018). *Fecal incontinence* is associated with the loss of voluntary control of the anal sphincter, atonic or hypotonic sphincter, low rectal compliance, low anal pressure at rest, and uninhibited rectal contractions (Lynch et al., 2001; Trivedi et al., 2016; Vallès & Mearin, 2009). It has been more frequently reported in subjects with lower motor neuron NB than in upper motor neuron NB (Inskip et al., 2018). Inadequate bowel management and use of laxatives also favor incontinence.

Abdominal pain is a frequent symptom, emerging later than neuropathic pain (in average 4.2 years after the injury) (Siddall, McClelland, Rutkowski, & Cousins, 2003). Its prevalence is over 30% in chronic SCIs (Nielsen, Faaborg, Christensen, Krogh, & Finnerup, 2017). It characterizes for being diffuse; some patients describe it as a prick, itch, warmth, or burning. It is closely associated with constipation, it worsens or improves with bowel movement.

Abdominal distension and flatulence are symptoms linked with constipation and fecal impaction. *Pathologies of the rectum and anus*, such as hemorrhoids, prolapse, anal fissures, rectal ulcers, and rectal bleeding, are favored by digital rectal stimulation (DRS), manual rectal evacuation (MRE), and the use of suppositories and enemas. Fecal impaction, anal fissures, and defecation routine per se are stimuli that trigger *autonomic dysreflexia* (Faaborg et al., 2014). Arterial hypertension may occur without accompanying symptoms that alert of AD (silent AD) (Kirshblum, House, & O'connor, 2002). The relevance of this lies on the fact that recurrent AD episodes associate with immunosuppression, involvement of cardiac mechanics, cerebrovascular changes, and cognitive impairment after SCI (Eldahan & Rabchevsky, 2018).

It is easy to understand that NBD due to its clinical manifestations and complications, negatively affect physical and psychological well-being, with a significant association between NBD severity and impact on QoL (Pires et al., 2018).

Diagnosis

The *medical history* is key to know the symptoms and their severity, patients' pathological background, and the medication being received. It must include the presence of sensation of defecation, diet, physical activity, frequency of bowel movements, stool consistency, and tested strategies for bowel management. The Bristol scale is a useful instrument to assess stool consistency in a fast and simple way (Lewis & Heaton, 1997). The time spent in bowel toileting is particularly relevant; reducing this time is one of the aims of treatment. Recording a diary of defecation by de patient will allow knowing the response to therapeutic measures. Uniformity in data collection is important when comparing results. The International SCI Bowel Function Basic Data Set (Krogh et al., 2017) gathers the basic data on bowel function following SCI that may be used in clinical practice.

Physical examination includes general, neurological, and abdominal inspection, as well as of the anorectal area. Other aspects to assess are the functional ability, balance in sitting position, and presence of spasticity. *Examination of the anorectal area* allows assessing the sensitivity, anal sphincter tone, and voluntary contraction. The presence of anal and bulbocavernosus sacral reflexes are indicative of anorectal reflex activity.

General *blood tests* are very useful to assess patients' general condition, detect warning signs, or endocrine and metabolic disorders that may contribute to bowel dysfunction.

Plain abdominal X-ray is useful to assess the amount and distribution of stools in the colon and detect megacolon, fecal impaction, and volvulus.

Colonoscopy has the same indication as for the general population, although it requires a more intensive gut preparation than in subjects who are neurologically intact (Song, Svircev, Teng, Dominitz, & Burns, 2018).

Other tests not used routinely are the *measurement of CTT* (total and segmental) and *anorectal manometry*, which may help identify the primary physiopathological mechanism of the symptoms.

Assessment scales

Multiple scales allow measuring the symptoms in bowel dysfunction, primarily constipation and incontinence, as well as the impact it has on QoL, although few have been validated for the SCI population. The Cleveland Clinic Constipation Scoring System (Agachan, Chen, Pfeifer, Reissman, & Wexner, 1996) and the Wexner Continence Grading Scale (Jorge & Wexner, 1993), are frequently used in studies with SCI patients. The 36-Item Short Form Survey (Ware & Sherbourne, 1992) and the Fecal Incontinence Quality of Life questionnaire (Rockwood et al., 2000) are widely used instruments in QoL studies.

The Neurogenic Bowel Dysfunction Score (Table 2) is a scale developed and validated specifically for adult SCI patients (Krogh, Christensen, Sabroe, & Laurberg, 2006). It allows scoring the clinical symptoms of colorectal and anal

TABLE 2 Neurogenic bowel dysfunction score.

Items	Points
(1) Frequency of defecation	
Daily (0) Two to six times every week (1) Less than once a week (6)	
(2) Time used for each defecation	
0–30 min (0) 31–60 min (3) More than 1 h (7)	
(3) Uneasiness, headache, or perspiration during defecation	
No (0) Yes (2)	
(4) Regular use of tablets against constipation	
No (0) Yes (2)	
(5) Regular use of drops against constipation	
No (0) Yes (2)	
(6) Digital stimulation or evacuation of the anorectum	
Less than once every week (0) Once or more every week (6)	
(7) Frequency of fecal incontinence	
Less than once every month (0) One to four times every month (6) One to six times every week (7) Daily (13)	
(8) Medication against fecal incontinence	
No (0) Yes (4)	
(9) Flatus incontinence	
No (0) Yes (2)	
(10) Perianal skin problems	
No (0) Yes (3)	
Total NBD score (range 0–47)	
NBD score	**Bowel dysfunction**
0–6	Very minor
7–9	Minor
10–13	Moderate
14 or more	Severe

10-Item score scale. A score of 0–47, the higher score indicates more severe bowel symptoms.
Modified from Krogh, K., Christensen, P., Sabroe, S., & Laurberg, S. (2006). Neurogenic bowel dysfunction score. *Spinal Cord, 44*(10), 625–631.

dysfunction; the importance of each item was established based on the strength of its association with self-perceived QoL. The greater the scoring, the greater the impact on QoL (Adriaansen, van Asbeck, van Kuppevelt, Snoek, & Post, 2015).

Conservative treatment of the neurogenic bowel

General recommendations

First, it is convenient to check the medications the patient is taking and make adjustments on those that might be contributing to the symptoms. Analgesics, anti-cholinergics, anti-depressants, and anti-psychotics, as well as iron supplements and aluminum compounds, which favor constipation. Excessive use of laxatives favors fecal incontinence, abdominal pain, and flatulence. Assessing the eating habits of the patient is also important.

Diet

Stool volume and consistency can be regulated through diet. Low *fluid* intake increases the probability of suffering constipation. On the other hand, high intake (>2 L/day), may be associated with prolonged bowel care (Engkasan & Sudin, 2013). Recommendation on fluid intake should be tailored and balanced with the type of bladder management.

Fiber helps increase fecal mass and its capacity to retain water. Consequently, colonic transit is accelerated and feces become softer. Although there are no accepted recommendations for SCI, an initial daily intake of 15 g of dietary fiber is suggested, monitoring the effect, and if necessary, increase the amount of fiber slowly and gradually, taking into account that high-fiber diets (30 g/day) may increase CTT in these patients (Cameron, Nyulasi, Collier, & Brown, 1996).

Physical exercise

Regular *physical exercise* may improve constipation symptoms, as it affects bowel motility, speeding up the colonic and gut transit time, and stimulates abdominal muscles helping move fecal matter toward the rectum (Gao et al., 2019). In people with SCI, standing seems to improve bowel function, although this has not been demonstrated in clinical trials (Kwok et al., 2015).

Abdominal massage

The mechanisms suggested to explain the effect of abdominal massage on the bowel are the increase of abdominal pressure and improvement of peristalsis. It may be performed during bowel routine to help pass stool. Fifteen minutes of *abdominal massage* following digital stimulation, decreases CTT, abdominal distension and fecal incontinence, and increases the frequency of defecation (Ayaş, Leblebici, Sözay, Bayramoğlu, & Niron, 2006). Similarly, *electrical stimulation of the abdominal muscles* during the bowel care program shortens the time until the feces come out and total time of bowel care (Korsten et al., 2004).

Mechanical techniques to ease bowel movements

Digital rectal stimulation (DRS) dilates the anal canal relaxing the puborectalis muscle, which reduces the resistance of stool to come out, triggers rectal contraction, and increases contractile activity of the descending and sigmoid colon (Korsten et al., 2007). ***Manual rectal evacuation*** (MRE) of feces is the most frequent form of bowel evacuation in some series (Coggrave, Norton, & Wilson-Barnett, 2009; Savic, Frankel, Jamous, Soni, & Charlifue, 2018). It is often the only effective way to empty the bowel in patients with areflexic bowel. In subjects with reflex function, MRE may be necessary to complete the emptying process (Coggrave et al., 2009) (Table 3).

Pharmacological treatment

Drugs that act on the colon are primarily used, aiming to increase its motility or change the texture of the stools (Table 4). Rectal administration of medication is used to ease defecation.

TABLE 3 Interventions for defecation.

Mechanical interventions			
Digital rectal stimulation			
Manual evacuation (digital removal of feces)			
Pharmacological interventions			
	Presentation	**Mechanism of action**	**Characteristics**
Glycerine	Suppositories, microenemas (5–10 mL)	Stimulant and osmotic laxative	Effective in 15–30 min Side effects: Irritation, stinging, anal itching
Bisacodyl (with a polyethylene glycol base or a hydrogenated vegetable oil base)	Suppositories	Stimulant laxative	Effective in 10–30 min Side effects: Abdominal pain and diarrhea
Docusate sodium or calcium	Microenemas (5–10 mL)	Stool softener	Effective in 2–15 min
Sodium citrate, sodium lauryl sulfoacetate, sorbitol	Microenemas (5–10 mL)	Osmotic laxative	Effective in 5–15 min Side effects: Abdominal pain and diarrhea
Sodium phosphate	Enemas (80, 140, 250 mL)	Saline laxative	Effective in 1–5 min Side effects: Abdominal bloating and pain, vomiting, renal impairment

Mechanical and pharmacological techniques to trigger defecation. Unpublished.

TABLE 4 Pharmacological treatment of neurogenic bowel.

	Mechanism of action	Active principle	Onset of action	Side effects
Oral laxatives				
Bulk-forming laxatives	Retain fluid in the stool increasing its weight and consistency, stimulate peristalsis and soften fecal matter	Psyllium Methylcellulose	24–72 h	Abdominal bloating, and flatulence
Stool softeners laxatives	Tensioactive agents which soften and lubricate fecal matter	Docusate sodium	24–72 h	Inhibition of gallbladder secretion, gastric mucosal lesions, anorexia, nausea and vomiting
		Liquid paraffin	6–8 h	Irritation of rectal mucosa, aspiration pneumonitis
Osmotic laxatives	Create an osmotic gradient drawing fluid into the intestinal lumen and promoting peristalsis and stool propulsion	Lactitol Lactulose	1–3 days	Cramping, abdominal bloating, and flatulence
		Polyethylene glycol (macrogol)	1–4 days	Diarrhea, nausea, abdominal bloating and pain, flatulence
		Magnesium and sodium salts	0.5–3 h	Electrolyte imbalance
Stimulant laxatives	Stimulate intestinal mucosal, decrease fluid and electrolyte absorption	Bisacodyl	6–12 h	Cramping, electrolyte imbalance with chronic use
		Sodium picosulfate	6–9 h	
		Sennosides A and B	8–12 h	Cramping, nausea, abdominal bloating and pain

TABLE 4 Pharmacological treatment of neurogenic bowel—cont'd

	Mechanism of action	Active principle	Onset of action	Side effects
Prokinetic agents				
	Highly-selective serotonin 5-HT4 receptor agonist	Prucalopride		Peak plasma concentration achieved in 2–3 h Requires dose adjustment in renal failure Side effects: headache, nausea, diarrhea, abdominal pain
	Inhibits the hydrolysis of acetylcholine by competing with acetylcholine for attaching to acetylcholinesterase	Neostigmine		Bradycardia, bronchoconstriction

Main oral laxative and prokinetic drugs for the treatment of constipation, including its active principle, mechanism and starting action, and the most frequent side effects. Unpublished.

Rectal laxatives

Suppositories or micro-enemas, alone or in combination with DRS and MRE, are used to trigger defecation. Patients whose rectal-anal reflexes are preserved respond to pharmacological stimulation, although the effectiveness and response time may vary greatly. The most commonly used chemical stimulants are *bisacodyl* and *glycerin*. Large-volume *phosphate enemas* are not routinely used for the chronic management of constipation in SCI patients, although they may be useful in cases of fecal impaction (Table 3).

Oral laxatives

Although they have been used for a long time, there is limited available evidence on their effectiveness and safety (Coggrave, Norton, & Cody, 2014). Bulk-forming and non-saline osmotic are the most commonly used oral laxatives. The choice depends on several factors such as its mechanism of action, speed of onset and duration of effect.

Prokinetics

Prokinetics promote bowel transit by reducing the passage time of stools through the bowel. *Metoclopramide* and *erythromycin* have no effect on colonic motility. They are frequently used for treating gastric dilatation and paralytic ileus, characteristic of the spinal shock phase.

Reduction in CTT has been shown with *prucalopride*, as well as improvement in the frequency of bowel evacuations in SCI patients. No significant improvement was shown for the duration of bowel care, episodes of fecal incontinence, or need for digital evacuation (Krogh et al., 2002).

In people with SCI, *neostigmine* given with glycopyrrolate improves the evacuation and reduces the time of bowel care (Korsten et al., 2005; Rosman et al., 2008). Their cardiovascular and pulmonary adverse effects and parenteral administration limit a chronic use of these types of medication. Recently, good results were reported with transdermal delivery by iontophoresis (Korsten et al., 2018).

Other drugs

Fampridine increases the days of bowel movements in patients with incomplete SCI (Cardenas et al., 2007). *Oxymetazoline* topical gel may help treating fecal incontinence (Barak, Gecse, & Takács, 2019). Other drugs such as *botulinum toxin, colchicine, lubiprostone, and linaclotide* have shown to be effective in chronic constipation and NB of different etiology, although it has not been studied in SCI patients.

Bowel program

The establishment of an early routine bowel program is considered the best practice for SCI patients (Qi, Middleton, & Malcolm, 2018; Stoffel, Van der Aa, Wittmann, Yande, & Elliott, 2018). The aim is to achieve regular, predictable, effective evacuation, as well as to eliminate or minimize incontinence episodes and other secondary complications of NB. Between 56% and 84.8% of the patients will achieve a satisfactory bowel management with the program (Adriaansen et al., 2015; Correa & Rotter, 2000; Engkasan & Sudin, 2013).

The bowel program is the establishment of an evacuation routine following a scheme that sets the moment during the day and frequency at which the routine is going to be carried out. Furthermore, it includes dietary recommendations, oral laxatives, and use of rectal stimulation and/or manual bowel evacuation. The program is different for each patient based on the main symptom, the characteristics of the SCI and presence or absence of sacral reflexes. Most patients will require more than one intervention to reach an effective bowel management. The key for a successful program lies largely on education and training.

The first recommendation is to schedule a regular *frequency and time*. In general, it is advisable to empty the bowel every 48 h to achieve a minimum of three bowel movement every week (Coggrave, Burrows, & Durand, 2006; Correa & Rotter, 2000). A lower frequency or irregular care contributes to constipation and impaction episodes. Patients with areflexic NB, with high risk of incontinence, may need to empty their bowel on a daily basis or even twice a day.

The patient has to establish the time based on his/her needs. Routine is a key element in the program and must be repeated at the same time. It is recommended to perform it 20–30 min after the main meal to take advantage of bowel's increased physiological motility after a meal (gastrocolic reflex) (Suttor et al., 2009).

The patient should preferably be in a sitting position in the toilet and an adapted environment is essential. The need of technical aids will be assessed, i.e., a bathtub stool, side handles, and a toilet seat riser. When the patient has a fragile equilibrium, the program will be carried out in the bed, preferably in the left lateral decubitus position (Ozisler et al., 2015).

For optimum stool consistency and to promote colonic transit, dietary adjustments or an oral laxative may be necessary.

For the act of defecation, a triggering stimulus is usually needed (DRS, suppositories, or micro-enema) (Table 3). MRE may also be necessary as the only emptying method, before the administration of a suppository or DRS, or subsequently, to complete the emptying. Some physical activity can be recommended before the programmed bowel movement, as well as abdominal massage during the process.

There are some differences in the program between reflex and areflexic NB patients (Table 5). Thus, in subjects with reflex NB bowel movement may be achieved with chemical rectal stimulants, DRS, or a combination of both. In some cases, taking a stimulant laxative before the program may be of help, although it is not advisable to do this as a routine. In patients in which sacral reflexes are not preserved, digital rectal and pharmacological stimulation are ineffective and MRE should be used. Stools should be firm in these patients to facilitate manual evacuation and decrease the risk of incontinence in cases of sphincter hypotony or atony. Anal plugs may be effective when there is fluid or gas loss in small volumes.

A well-established program must achieve the shortest possible time spend in bowel care. If it takes more than an hour, it must be assessed to identify which elements need to be corrected. Patients must know how SCI affects the function of their bowel. NBD must be part of the regular follow-up during SCI chronic phase.

TABLE 5 Bowel care in neurogenic bowel.

	Hyperreflexic neurogenic bowel	Areflexic neurogenic bowel
	Presence of sacral reflexes Injury above the medullary cone	Absence of sacral reflexes Injury in medullary cone and cauda equina
Frequency	Daily or alternate days	Daily or twice a day
Consistency of feces	Soft, Bristol 4	Hard, Bristol 3
Defecation	DRS, suppository, microenema	Manual rectal evacuation
Supporting measures	After meals, exercise, abdominal massage	After meals, exercise, abdominal massage

Outline bowel care program according to hyperreflexic vs areflexic neurogenic bowel. *DRS,* digital rectal stimulation. Unpublished.

Anorectal biofeedback

Biofeedback is a reeducation technique through feedback of bowel movement and continence. This treatment modality is scarcely use in NBD, but may be beneficial in people with incomplete motor SCI (Mazor, Jones, Andrews, Kellow, & Malcolm, 2016).

Transanal irrigation

Transanal irrigation (TAI) allows performing a programmed defecation and is a technique for treating bowel dysfunction in SCI patients. Some studies show that it improves constipation, incontinence, shortens the time spent in bowel care, reduces the intake of medications, and improves QoL (Christensen et al., 2006; Faaborg et al., 2009). Good results have been reported in 68% and 63% of patients with incontinence and constipation, respectively (Del Popolo et al., 2008).

The most used systems are cones or rectal balloon catheters, a recipient for water and an infusion set-up. The *infusion* may be carried out through manual pumping (Fig. 1A) or using an electronic control unit (Fig. 1B) in which the volume of water to be infused, the speed of the infusion, and the size of the balloon are programed.

The *irrigation fluid* is usually warm tap water (36–38°C). The instilled volume may vary, generally starting with 500 mL and increased up to 1000 mL.

As with the classical bowel care program, stool consistency should be optimized if necessary. The recommendations to establish a routine at a specific time of the day and perform the irrigation 20–20 min after the meal are maintained. Initially, it is advisable to carry out this on a daily basis and reduce the frequency considering the preferences and needs of the patient.

Absolute *contraindications* for TAI include anal or rectal stenosis, colorectal cancer, inflammatory bowel disease, and recent colonic surgery (Emmanuel et al., 2013). Up to 48% of subjects my suffer *adverse effects* such as abdominal pain or discomfort, rectal bleeding, fatigue, general malaise, sweating, perianal discomfort, nauseas, tremors, headache, and facial redness (Faaborg et al., 2009). Rectum perforation is rare, although it is a potential risk (Christensen et al., 2016; Faaborg et al., 2009). TAI is also a trigger of AD.

Surgical treatment of the neurogenic bowel

Electrical stimulation

Both, neurostimulation and neuromodulation, have been investigated for the treatment of NBD. The goal of ***sacral neuromodulation*** is to adjust and reestablish the balance between the inhibitory and facilitatory reflexes that control the functional activity of the pelvic floor. Some studies suggest this therapy improves bowel function in patients with incomplete SCI (Chen & Liao, 2015; Lombardi, Del Popolo, Cecconi, Surrenti, & Macchiarella, 2010). To date, a widespread use cannot be recommended. The effect on bowel function of ***stimulating the pudendal nerve*** has also been assessed in patients with complete cauda equina lesions (George et al., 2014). Short-term results seem encouraging, showing improvement of constipation and incontinence. ***Sacral anterior root stimulation*** requires a sacral dorsal root rhizotomy with subsequent implantation of a stimulator in the anterior sacral roots S2–S4. Although this system was designed for treating neurogenic bladder in SCI, some patients use it as a method for bowel emptying with reported good results (Rasmussen et al., 2015; Vallès, Rodríguez, Borau, & Mearin, 2009).

Antegrade continence enema

A continence tube is created, generally an appendicostomy, which allows intermittent catheterization for colonic irrigation. This procedure has been used in SCI patients, showing improvement of QoL associated to fecal incontinence (Smith & Decter, 2015).

Colostomy and ileostomy

An invasive procedure, not exempt from complications, which should be indicated to selected patients when other more conservative treatment methods fail.

The most common indications are constipation and unmanageable fecal incontinence, extended bowel care time, AD or pain during defecation; it is also performed to facilitate the healing of pressure sores or infections in the perineum or abdomen. Left-side colostomies maintain better the colonic surface and prevent excessive loss of water, facilitate stoma care, and there is much lower risk of leakage (Safadi, Rosito, Nino-Murcia, Wolfe, & Perkash, 2003). With right-side

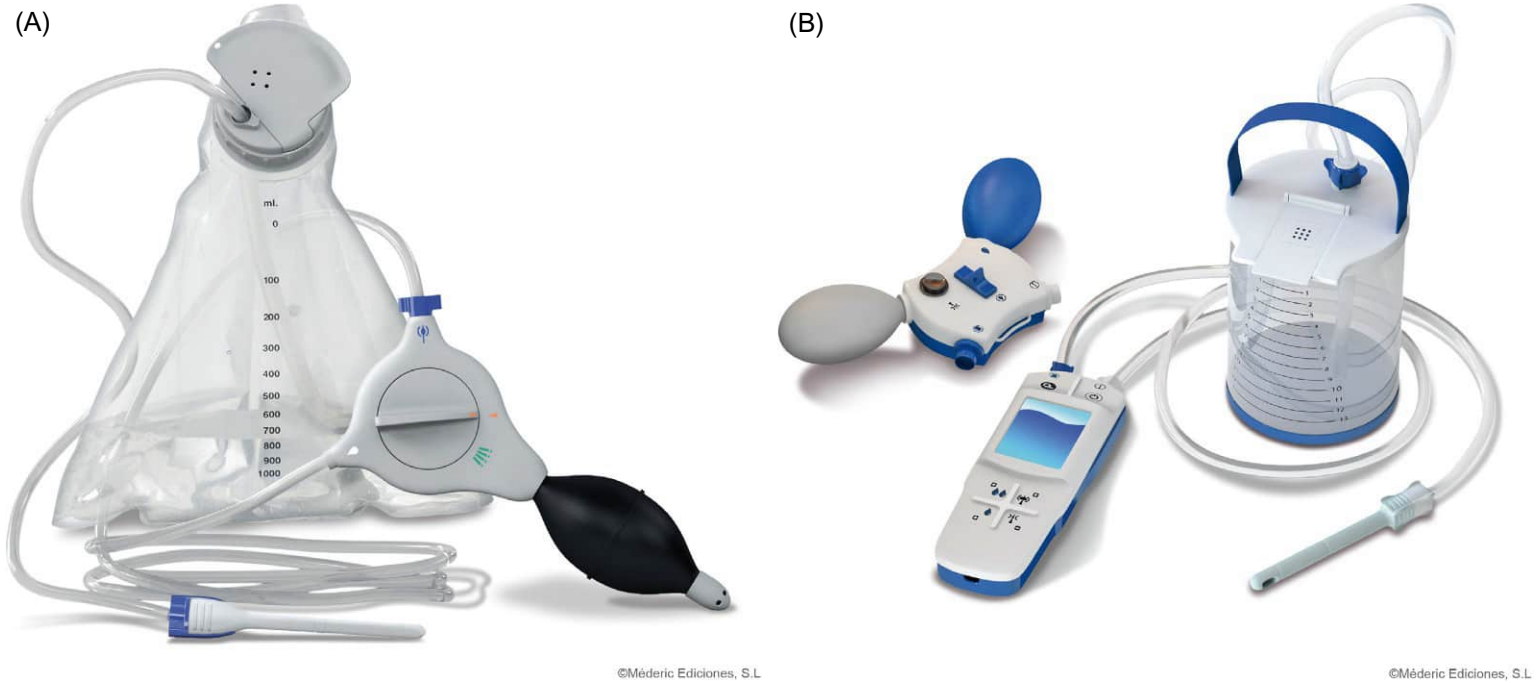

FIG. 1 Transanal irrigation devices. (A) Transanal irrigation device with manual pumping; (B) transanal irrigation device using an electronic control unit. *(With permission of Mederic Ediciones S. L.)*

ileostomies or colostomies, there is less emptying problems. Results from different studies report that they simplify and reduce bowel care time, decrease the number of bowel dysfunction-related hospitalizations, and provide equal or better QoL (Rosito, Nino-Murcia, Wolfe, Kiratli, & Perkash, 2002). Patients are usually satisfied with the surgery and a high percentage communicates that he/she would have undergone surgery earlier (Safadi et al., 2003). Despite the good results, this method is scarcely used; between 2.4% and 8% have undergone a colostomy aimed at bowel care (Adriaansen et al., 2015; Coggrave et al., 2009; Pardee, Bricker, Rundquist, MacRae, & Tebben, 2012).

Conclusions

With the current knowledge on NBD, its therapeutic management remains empirical, based on a step-up approach going from conservative to more invasive options (Fig. 2). It can be predicted that advances in pharmacological research and control of nervous system function through electrical stimulation will provide in-between treatment options.

Applications to other areas of neuroscience

Bowel disturbance is one of the sequelae of spinal cord injury that most affects the life of these patients; however, it is possibly the less studied condition. Advancement in developing successful treatments for neurogenic bowel dysfunction has been slow in part due to the absence of reliable and validated tools to assess neurogenic bowel dysfunction-related symptoms and complications, both from the perspective of the patient and the physician. Therefore, the standardization of validated scales aimed at this group of patients and the further development of quality of life measurement tools specifically associated with intestinal dysfunction will help advance the evaluation, research and better management of neurogenic bowel dysfunction.

On the other hand, it is necessary to develop and improve tools such as colonic transit time, manometry and others, that provide more objective assessment, needed in therapeutic decision-making and in research studies on new treatment approaches.

Although spinal cord injury is the condition most frequently associated with neurogenic bowel dysfunction, any patient suffering from central nervous system disease may experience symptoms of intestinal dysfunction. Neurological conditions such as multiple sclerosis, cerebral palsy, stroke, or Parkinson's disease, placing the individual at risk for constipation and incontinence. Although the presentation of intestinal dysfunction in these conditions can vary, the underlying cause is also the damage to the nervous control of the bowel. Advances in the knowledge of physiopathology and management of bowel dysfunction in SCI may help improve bowel care in other neurological pathologies causing neurogenic bowel dysfunction.

Finally, accurate spinal cord injury bowel dysfunction understanding, and improvement of diagnostic methods may contribute, without doubt, to the assessment of new therapeutic approaches for the treatment of spinal cord injury currently being developed, such as cell therapies or medullary stimulation.

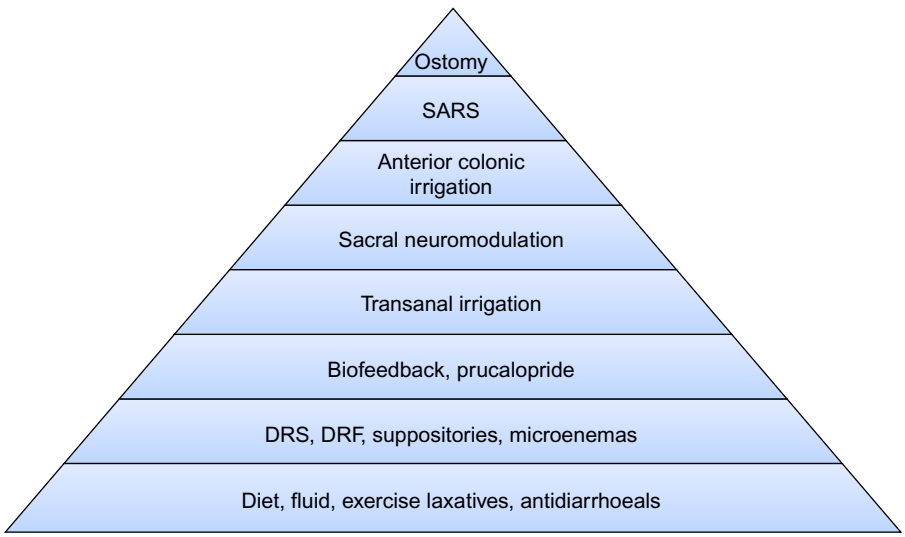

FIG. 2 Treatment options in neurogenic bowel dysfunction management. The pyramid represents a stepwise treatment from conservative measures to more invasive measures. *SARS*, sacral anterior root stimulation; *DRS*, digital rectal stimulation; *DRF*, digital removal of feces. Unpublished.

Dictionary of terms

Abdominal massage: Massage applied to the abdomen in a clockwise direction using the hand.
Anal reflex: Visible contraction of anus in response to pinprick of surrounding skin.
Autonomic dysreflexia: Abnormal sympathetic nervous system response to a noxious stimulus below the level of injury in individuals with spinal cord injury above the seven thoracic levels. The guiding symptom is arterial hypertension.
Bowel care: Number of different interventions combined in a bowel routine to promote effective and timely fecal evacuation.
Bulbocavernosus reflex: Contraction of anus in response to pressure on glans penis or clitoris.
Colonic transit time: Time it takes for stool to pass through the colon.
Dietary fiber: Carbohydrate polymers with 10 or more monomeric units, which are not hydrolyzed by the endogenous enzymes in the small intestine of humans.
Digital rectal stimulation: Technique performed by inserting lubricated finger through the anal canal into the rectum and slowly rotating the finger in a circular movement maintaining contact with rectal mucosa.
Digital removal of feces: Technique performed by insertion of a single gloved, lubricated finger into the rectum to break up or remove stool.
Neurogenic bowel or neurogenic bowel dysfunction: Colonic dysfunction as result of central neurological disease or damage.
Transanal irrigation: Procedure that involves introducing water into de colon through the anus to evacuate the distal colon and rectum.

Key facts of neurogenic bowel dysfunction

- Neurogenic bowel affects to a greater or lower degree most spinal cord injured patients; around 50% perceive restrictions in their quality of live or social activities.
- Spinal cord injury causes colon and rectum innervation changes that lead to loss of voluntary control of defecation, bowel motility impairments, and changes in sphincter tone.
- Fecal incontinence, constipation, and a combination of both are the primary manifestations.
- Based on the level of spinal cord injury, two neurogenic bowel dysfunction patterns are distinguished: hyperreflexic and areflexic.
- The diagnostic assessment is mainly clinical. Assessment scales allow estimating the seriousness of the symptoms and response to treatment.
- Neurogenic bowel dysfunction treatment is largely empirical.

Summary points

- Slower colonic transit, increased colonic tone, changes in rectal compliance, of the tone and sensitivity of the sphincter, and lack of relaxation of the sphincter, are the mechanisms responsible of neurogenic bowel symptoms in spinal cord injury.
- Secondary disturbances in enteric nervous system, colonic neuromuscular structures, and bowel microbiota may be contributing factors.
- Establishing a bowel emptying routine together with a technique that triggers defecation, remains the treatment of choice.
- Optimizing stool consistency through diet and/or a bulk-forming or osmotic laxative may be necessary.
- Transanal irrigation is a treatment modality for effective bowel emptying in cases in which control is not achieved with the bowel program.
- Invasive treatments are an option in selected cases. Colostomy may improve the quality of life in these patients.

Chapter 21

Management of neurogenic lower urinary tract dysfunction due to spinal cord injury

Noritoshi Sekido

Department of Urology, Toho University Ohashi Medical Center, Meguro-City, Tokyo, Japan

Abbreviations

AC	augmentation cystoplasty
AD	autonomic dysreflexia
AUS	artificial urinary sphincter
BNR	bladder neck reconstruction
BNS	bladder neck sling
BOO	bladder outlet obstruction
BoNT-A	type A botulinum toxin
CIC	clean intermittent catheterization
DO	detrusor overactivity
DSD	detrusor sphincter dyssynergia
DU	detrusor underactivity
FVC	frequency volume chart
HCC	hydrophilic-coated catheter
LUT	lower urinary tract
NLUTD	neurogenic lower urinary tract dysfunction
PAG	periaqueductal gray
PMC	pontine micturition center
PVR	postvoid residual
QOL	quality of life
PVC	polyvinyl catheter
SARS	sacral anterior root stimulation
SCI	spinal cord injury
SNM	sacral neuromodulation
UI	urinary incontinence
UTI	urinary tract infection
UUT	upper urinary tract
VUDS	video-urodynamic study

Introduction

Since Sir Ludwig Guttmann introduced sterile intermittent catheterization in the 1940s at Stoke Mandeville Hospital (Guttmann & Frankel, 1966), management of lower urinary tract (LUT) dysfunction has been an important part of the clinical practice of patients with spinal cord injury (SCI). This chapter begins with a brief overview of normal LUT function and pathophysiological aspects of neurogenic LUT dysfunction (NLUTD) due to SCI. Then, it outlines the key points of assessment as well as treatment of LUT dysfunction according to the pathway of management of patients with NLUTD due to SCI, as shown in Fig. 1.

Diagnosis and Treatment of Spinal Cord Injury. https://doi.org/10.1016/B978-0-12-822498-4.00021-X

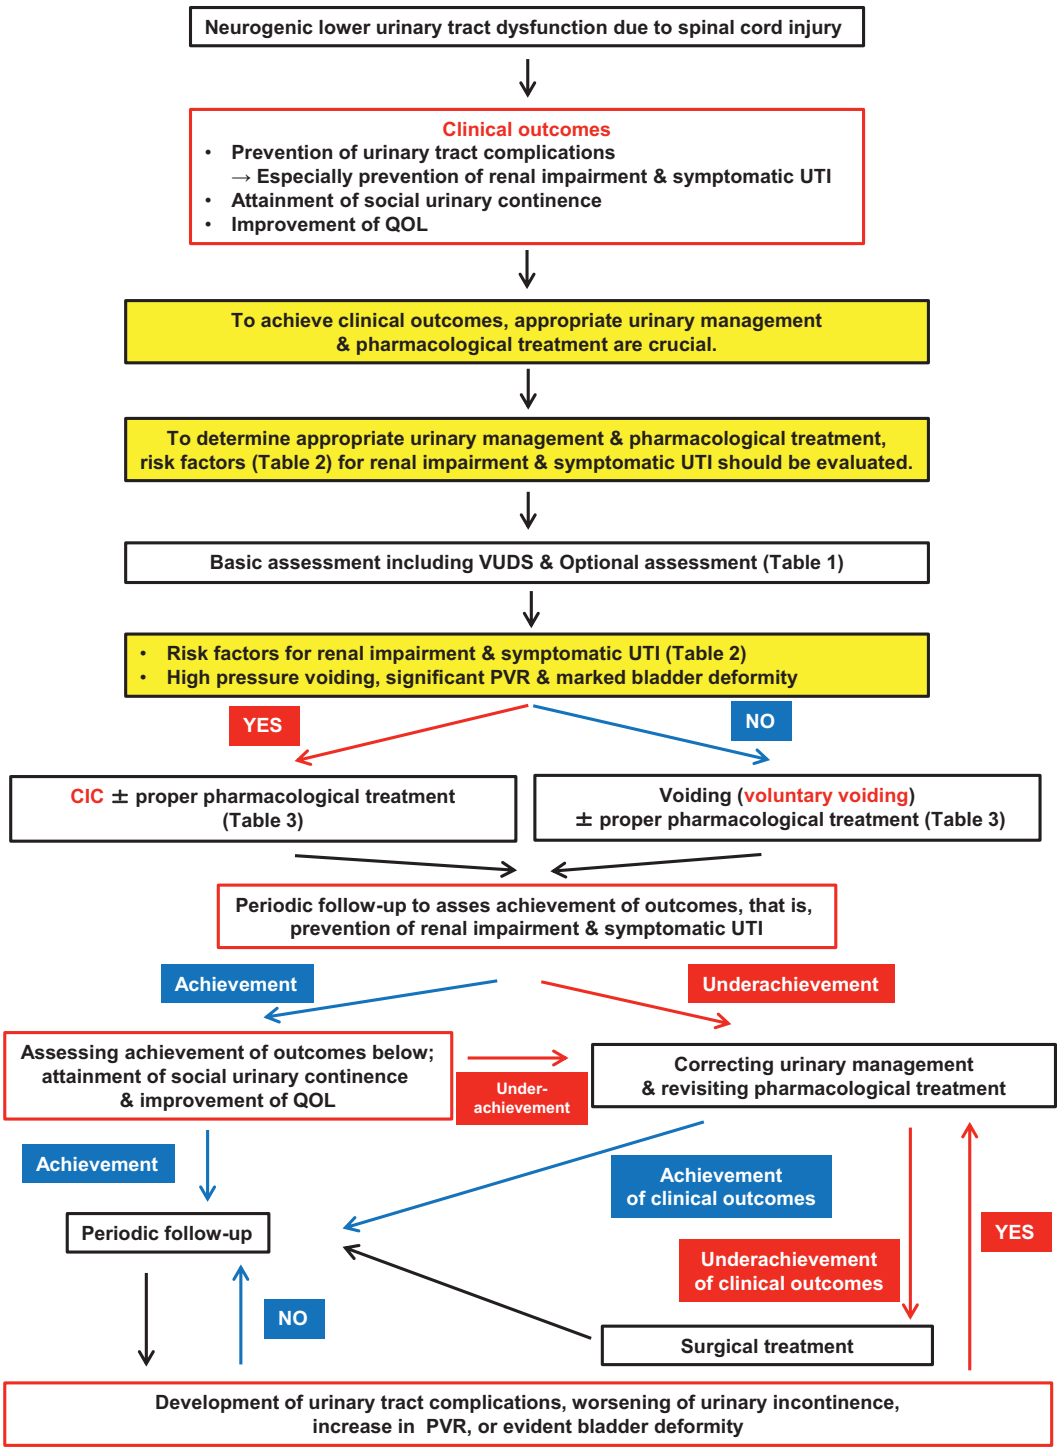

FIG. 1 Clinical pathway of management of patients with neurogenic lower urinary tract dysfunction due to spinal cord injury. Please see "Pathway of NLUTD management" section for details. To achieve the prevention of renal impairment and symptomatic UTI, proper urinary management and pharmacological treatment are determined, based on the basic and optional assessment. Then, further treatment will be considered if these outcomes are not achieved, or obtaining social urinary continence is warranted. *CIC*, clean intermittent catheterization; *PVR*, postvoid residual; *QOL*, quality of life; *UTI*, urinary tract infection; *VUDS*, video-urodynamic study.

Physiology of storage and emptying

The urinary tract consists of the upper urinary tract (UUT) and LUT. While UUT includes the kidneys and ureters, LUT includes the urinary bladder and urethra with the external urethral sphincter. During the storage phase, the bladder gradually distends, which activates myelinated A-delta afferent fibers mainly entering S2 to S4 (de Groat, Griffiths, & Yoshimura, 2015). Then, information about bladder filling ascends the spinal cord and stimulate sympathetic nerves innervating the LUT as well as the pudendal nerve innervating the external urethral sphincter, while eventually reaching the periaqueductal gray (PAG), from which the information is relayed to the relevant areas of the brain (Griffiths, 2015). Ultimately, the medial prefrontal cortex probably determines urine storage or bladder emptying (Griffiths). Once a decision is made to empty the bladder, the medial prefrontal cortex activates the pontine micturition center (PMC) via PAG (Griffiths).

In terms of the peripheral nervous system during the storage phase, the sympathetic nerves from T10 to L1 relax the detrusor via β3-adrenoceptors and contract smooth muscle from bladder neck to proximal urethra via α1-adrenoceptors (de Groat et al., 2015). In addition, the pudendal nerve from S2 to S4 (Onuf's nucleus) controls external urethral sphincter activity (de Groat et al., 2015). These nerve activities result in urine storage at low pressure and of sufficient volume without urinary incontinence (UI). During the emptying phase, once PMC is activated, the parasympathetic nerves from S2 to S4 contract the detrusor via muscarinic receptors (M3 receptors), while sympathetic and pudendal nerves are inhibited, resulting in residual-free voiding with good urinary flow without high pressure (de Groat et al., 2015). The coordination between the detrusor and external urethral sphincter during the emptying phase requires intact neural pathways between PMC and the sacral cord.

Pathophysiology of NLUTD due to SCI

Classification of NLUTD due to SCI

NLUTD due to SCI is divided into two types: supra-sacral NLUTD due to damage above the sacral cord, and sacral NLUTD due to damage to the sacral cord (Sekido et al., 2020). During the acute phase of SCI (spinal shock phase), LUT in the supra-sacral NLUTD reveals an acontractile detrusor with a closed bladder outlet, which lasts about for a few weeks to 3 months. However, a recent report warned that unfavorable urodynamic findings leading to high intravesical pressure were found in two-thirds of patients even during the spinal shock phase (Bywater, Tornic, Mehnert, & Kessler, 2018). In the chronic phase, the supra-sacral NLUTD is characterized by detrusor overactivity (DO) with a discordant external urethral sphincter (detrusor sphincter dyssynergia, DSD), resulting in high-pressure storage as well as emptying. DO can causes reflex UI. In addition, besides DSD during the emptying phase, detrusor underactivity (DU) due to disruption of signal transmission from supra-spinal centers to the sacral cord may contribute to emptying dysfunction (Osman et al., 2014). The sacral NLUTD is characterized by impaired detrusor contractility (DU or acontractile detrusor) with an incompetent urethral closure mechanism (intrinsic sphincter deficiency, ISD) during storage and inadequate urethral relaxation (nonrelaxing sphincter) during emptying, resulting in refractory stress UI as well as incomplete bladder emptying. The bladder sensation is reduced or absent regardless of the level of injury.

Association between neurological level of SCI and NLUTD

The neurological level of SCI is represented by the lowest segment of the cord with residual function, which corresponds to the upper limit of the extent of SCI. On the other hand, as described above, NLUTD is classified according to whether the lower limit of SCI involves the sacral cord. Therefore, it is difficult to accurately predict the NLUTD condition based on the neurological level of SCI regardless of its completeness of SCI, and a video-urodynamic study (VUDS) is required for the assessment of the status of NLUTD after the end of the spinal shock phase (see "Basic and Optional assessments" section).

Elderly SCI

Elderly SCI is characterized by incomplete cervical SCI without bone injury, and central cord syndrome (Chan et al., 2018). Central cervical SCI damages the function of the upper extremities much more than the lower extremities, and the patients often recover well except for impaired hand dexterity. Theresultant impairment in hand dexterity poses serious problems for implementing clean intermittent self-catheterization. While the incidence of LUT dysfunction was reported to be low (Merriam, Taylor, Ruff, & McPhail, 1986), unfavorable urodynamic findings such as DSD were higher than previously reported, and some patients manifested urinary tract complications (Smith, Kraus, Nickell, & Boone, 2000). Therefore, in patients with NLUTD due to central cord injury, VUDS should be performed to assess NLUTD, and regular urological

surveillance is mandatory. Moreover, it should be noted that aging in SCI patients worsens their daily life activities, and eventually converts clean intermittent self-catheterization to indwelling catheterization (Chan et al., 2018). Besides this, renal impairment due to NLUTD or diseases other than NLUTD, urolithiasis, and cognitive impairment due to an excessive anti-cholinergic load should be carefully monitored in these patients (Chan et al., 2018; Welk & McArthur, 2020).

Overview of management of patients with NLUTD due to SCI

Clinical outcomes of management of NLUTD

The critical clinical outcomes or goals of the clinical practice in NLUTD due to SCI are prevention of urinary tract complications [e.g., renal impairment (renal dysfunction/UUT deterioration), symptomatic urinary tract infection (UTI), urolithiasis, gross hematuria, urethral stricture, urethrocutaneous fistula, bladder cancer, and catheter obstruction], attainment of social urinary continence, and improvement of quality of life (QOL) (Sekido et al., 2020).

Pathway of NLUTD management

Recently, patient-reported outcomes have become more important in the field of NLUTD than before, and QOL has been increasingly included in clinical outcomes of treatment for NLUTD (Adriaansen et al., 2017). Even though improvement of QOL is crucial, prevention of urinary tract complications, some of which are closely related to the patient's survival, remains the most important clinical outcome to be achieved in patients with NLUTD due to SCI. Therefore, as shown in Fig. 1, in order to prevent urinary tract complications, the first step is to determine the appropriate urinary management and pharmacological treatment aimed at preventing urinary tract complications, especially renal impairment and symptomatic UTI. Once the appropriate urinary management and pharmacological treatment has been determined, periodic follow-up assesses whether this outcome has been achieved. If the clinical outcomes of prevention of renal impairment and symptomatic UTI are not achieved, correcting urinary management as well as revisiting pharmacological treatment should be considered. If these outcomes are achieved, obtaining social urinary continence and enhancing QOL are the subsequent important clinical outcomes. To this end, urinary management and pharmacological treatment should be optimized without compromising the outcomes of prevention of renal impairment and symptomatic UTI. Because UI is associated with poor QOL, strategies to attain social continence should be actively addressed with careful consideration of the individual patient's preference, characteristics, and social environment. When maximum conservative treatment fails to achieve the above outcomes, surgical intervention becomes an option in carefully selected patients.

Basic and optional assessments

All the patients with NLUTD due to SCI should be assessed by basic assessment (Table 1) (Sekido et al., 2020). The basic assessment includes a history taking (Zlatev, Shem, & Elliott, 2018), assessment of QOL (Costa et al., 2001; Pinder et al., 2012; Welk et al., 2018), focused physical and neurological findings (Sekido et al., 2020), a frequency volume chart (FVC) or a bladder diary, urinalysis, blood tests to screen for renal dysfunction (Goto, Kawasaki, Takemoto, Abe, & Namima, 2018), a morphological evaluation of the urinary tract usually assessed by abdominal ultrasound, measurement of postvoid residual (PVR) and uroflow in patients with voiding (Sekido et al., 2020), and VUDS (Kreydin et al., 2018; Sekido et al., 2020). In addition to the basic assessment, optional assessment may be performed, which includes static and/or dynamic renal scintigrams in cases of renal dysfunction or vesico-ureteral reflux, and cystourethroscopy in cases of suspicious of urethral pathology, anatomical bladder outlet obstruction (BOO), bladder stones, or bladder cancer (Sekido et al., 2020). VUDS and cystourethroscopy should be performed with caution against developing autonomic dysreflexia (AD) during examinations (Liu, Zhou, Biering-Sørensen, & Krassioukov, 2017). Performing the basic as well as optional assessment identifies the presence or absence of risk factors for renal impairment, symptomatic UTI, UI, and QOL (Table 2) (Sekido et al., 2020). In addition, the presence or absence of high-pressure voiding due to functional BOO, significant PVR (>100 mL) due to BOO or DU/acontractile detrusor, and marked bladder deformity defined as grade 2 (bladder having mild pseudodiverticula) or higher by Ogawa's classification should be noted (Sekido et al., 2020).

TABLE 1 Basic assessment.

Evaluations	Comments
History taking	• The level of injury: neurological findings due to SCI are essential in determining urinary management, as residual upper extremity function and the ability to hold a sitting position or open the legs are important factors for clean intermittent self-catheterization. • Urinary management during and after the acute phase • The presence or absence of symptomatic UTI, urinary incontinence, AD • Concomitant medications • The status of anorectal and sexual function • Current co-morbid diseases • Past medical and surgical histories
Assessment of QOL	• Qualiveen 30 • The Neurogenic Bladder Symptom Score • Intermittent Self-Catheterization Questionnaire
Focused physical and neurological examinations of the lumbosacral region	• Sensation in the perianal area • Ability to voluntarily contract the external anal sphincter • The presence or absence of anal reflex (S2–S5) and bulbospongiosus reflex (S2–S4)
Frequency volume chart (or bladder diary)	Useful for • Evaluating bladder storage function • Detecting nocturnal polyuria • Confirming proper frequency/interval of CIC • Measuring treatment outcomes
Urinalysis	Also need urine bacteriology in case of suspected symptomatic UTI
Blood chemistry	• Serum creatinine or cystatin C • For early detection of renal impairment, cystatin C is more useful than serum creatinine • Prostate-specific antigen for middle-aged or older male patients, if indicated
Transabdominal ultrasonography	Screening test for upper and lower urinary tract abnormalities, such as • Hydroureteronephrosis • Bladder wall thickening/trabeculation • Urolithiasis • Prostatic enlargement
Postvoid residual and uroflowmetry[a] in patients with voiding	• Screening test for lower urinary tract dysfunction in patients managed with voiding
Video-urodynamic study	• Indispensable functional examination for NLUTD due to SCI, regardless of complete or incomplete injury, because neurological levels of injury do not always predict the nature of NLUTD • Identification of risk factors for renal impairment, symptomatic UTI, and UI to provide convincing evidence for urinary management and pharmacological treatment • Assessment of AD during the micturition cycle • "As low as reasonably achievable (ALARA)" should be kept in mind

The basic assessment provides clues for the optional assessment and evidence for urinary management and pharmacological treatment.
AD, autonomic dysreflexia; *CIC*, clean intermittent catheterization; *NLUTD*, neurogenic lower urinary tract dysfunction; *QOL*, quality of life; *SCI*, spinal cord injury; *UTI*, urinary tract infection.
[a]*Only patients enabled to urinate on a uroflowmeter.*

Urinary management (Table 3)

Urinary management during acute phase

During an acute phase, an indwelling catheterization should be changed to CIC as soon as the general condition of the patient becomes stable and urine output decreases to approximately 1.5 to 2.0 L per day, because long-term indwelling catheterization will cause catheter-associated complications (Welk et al., 2018).

TABLE 2 Risk factors for clinical outcomes.

	Risk factors
Renal impairment (renal dysfunction[a]/upper urinary tract deterioration[b])	• Video-urodynamic findings: decreased maximal bladder capacity, high pressure, and/or sustained detrusor overactivity, detrusor sphincter dyssynergia, decreased bladder compliance, high detrusor leak point pressure • Urinary management: indwelling urethral catheterization, bladder reflex triggering • Level and severity of the injury: tetraplegia, complete paralysis
Symptomatic urinary tract infection[c]	• Video-urodynamic findings: vesico-ureteral reflux secondary to lower urinary tract dysfunction, that is, decreased maximal bladder capacity, detrusor overactivity, detrusor sphincter dyssynergia, decreased bladder compliance, high detrusor leak point pressure • Urinary management: indwelling urethral catheterization • Level and severity of injury: cervical cord injury, A or B on American Spinal Injury Association impairment scale
Urinary incontinence	• Video-urodynamic findings: detrusor overactivity, decreased bladder compliance, intrinsic sphincter deficiency
Quality of life	• Negative impact: indwelling catheterization, clean intermittent catheterization by attendants • Positive impact: fewer worries about and fewer restrictions arising from urinary incontinence, less concerns about urinary tract infection as well as deterioration of bladder function

The presence or absence of risk factors is relevant to management of lower urinary tract dysfunction.
[a]*Renal dysfunction: increased serum creatinine level, decreased glomerular filtration rate, or renal scarring on renal scintigraphy.*
[b]*Upper urinary tract deterioration: hydroureteronephrosis, vesico-ureteral reflux, febrile upper urinary tract infection, or upper urinary tract stones.*
[c]*Symptomatic urinary tract infection: significant bacteriuria, pyuria, and symptoms suggestive of urinary tract infection, such as discomfort and/or pain in renal or supra-pubic area in incomplete injury, cloudiness of urine, worsening of urine odor, development or worsening of urinary incontinence or leakage around the catheter, pain on micturition, worsening of spasticity discomfort/lethargy/anorexia, autonomic dysreflexia, and fever or chills, without any obvious causes for those findings and symptoms.*

Urinary management during chronic phase

The appropriate urinary management is guided by the presence or absence of risk factors for renal impairment and symptomatic UTI, as well as high-pressure voiding, significant PVR, and marked bladder deformity.

CIC

Patients who have risk factors and/or high-pressure voiding, PVR, or bladder deformity should be managed with CIC (Romo et al., 2018). Based on the VUDS findings, the physician should determine the frequency, timing, and interval of CIC. Proper education and instruction with adequate follow-up are of paramount importance in the long-term compliance and persistence of CIC as well as avoiding complications such as urethral trauma and stricture in male patients, gross hematuria, and symptomatic UTI (Biardeau & Corcos, 2016). In addition, clean intermittent self-catheterization is preferred to CIC by caregivers in terms of maintaining QOL (Adriaansen et al., 2017). In patients managed with CIC, treatment for asymptomatic pyuria/bacteriuria (asymptomatic UTI) with antibiotics is not recommended because there is a dearth of clear evidence supporting the use of antibiotics for prevention of symptomatic UTI and the emergence of drug-resistant bacteria is a major concern (Sekido et al., 2020). There are several different types of catheters available for CIC (Jeong & Oh, 2019; Li et al., 2013; McClurg et al., 2017; Sun, Comiter, & Elliott, 2018) and please see "Key Facts of Catheters for Clean Intermittent Catheterization."

Voiding

Patients who do not have the above hostile findings and can void voluntarily can be managed with voluntary voiding, which means that patients are able to store an adequate volume of urine at low pressure and to void without bladder reflex triggering or bladder expression (Sekido et al., 2020). Voiding with bladder reflex triggering is indicated only in carefully selected male cervical cord injured patients with good reflex bladder contractility who cannot be managed with CIC due to the patient's disabilities and/or the lack of caregiver supports (Romo et al., 2018; Sekido et al., 2020). Transurethral

TABLE 3 Urinary management.

Urinary management	Descriptions
Voiding	• Transurethral bladder emptying without any catheterization
Voluntary (spontaneous) voiding	• Coordinated physiologic voluntary voiding, that is, voluntary detrusor contraction simultaneously with voluntary urethral relaxation • No need of triggering or Crede/Valsalva maneuvers
Bladder reflex triggering	• Need of triggers such as percussion on supra-pubic area to induce micturition reflex • Often concomitant sphincterotomy to overcome DSD
Bladder expression	• Need of Crede and/or Valsalva maneuvers to empty bladder • Preferable to be replaced by CIC
CIC	• Usually per urethra but, in carefully selected patients unable to perform transurethral catheterization, per abdominal continent catheterizable channel • Low pressure and residual-free bladder emptying within low-pressure storage, if properly performed • Need of adherence to appropriate frequency/interval as well as individualized fluid intake to avoid bladder over-distension or high storage pressure • May be performed even by male and female patients with cervical cord injury at the level of C5B and C6B, respectively, with great difficulty, but in practice more residual functions are necessary.
Indwelling catheterization	• Long term bladder drainage method with indwelling catheters • The last resort due to risk of a variety of catheter-associated complications
Indwelling urethral catheterization	• Transurethral catheter drainage • 14–16 Fr caliber catheters with 5–10 mL balloon replaced every 2–6 weeks
Indwelling supra-pubic catheterization	• Percutaneous catheter drainage • Frequent need of spinal or general anesthesia and supra-pubic cystotomy at catheter insertion • Optional urinary management in patients with high cervical SCI • Avoidance of urethral complications • Use of larger (18–22 Fr) caliber catheters with short tips, resulting in less incidence of catheter blockage than indwelling urethral catheterization

This table describes the key urinary management for patients with spinal cord injury.
CIC, clean intermittent catheterization; *DSD*, detrusor sphincter dyssynergia.

sphincterotomy is often needed to achieve low-pressure storage as well as voiding without significant PVR and to prevent UUT deterioration (Takahashi, Kimoto, & Eto, 2018). Bladder expression with manual compression of the supra-pubic area (Crede maneuver) or straining (Valsalva maneuver) is not recommended as voiding because bladder expression is potentially urodynamically unsafe for the urinary tract due to the presence of a nonrelaxing urethral sphincter and should be replaced by CIC (Sekido et al., 2020).

Indwelling catheterization

Generally speaking, indwelling catheterization is not recommended for urinary management of patients with SCI due to a constellation of unavoidable catheter-associated complications, such as symptomatic UTI, urolithiasis, catheter blockage/obstruction, AD, and bladder cancer (Igawa, Wyndaele, & Nishizawa, 2008; Sekido et al., 2020). This type of urinary management is mainly indicated for patients with cervical SCI who cannot be managed with CIC (Sorokin & De, 2015). Supra-pubic catheterization may be better than urethral catheterization in terms of freedom from urethral or genital complications such as urethral trauma, urethral diverticula, urethrocutaneous fistula, epididymitis, or intrascrotal abscess (Feifer & Corcos, 2008; Hunter, Bharmal, & Moore, 2013; Igawa, et al., 2008). On the other hand, the intermittent (temporary) use of an indwelling urethral catheter is an option for patients with nocturnal polyuria and/or difficulty in performing CIC away from home (Ozawa et al., 2005; Sekido et al., 2020; Sturm, Cantrell, Durbin-Johnson, & Kurzrock, 2020). For example, a specialized indwelling catheter for this purpose (Fig. 2) has been approved in Japan, and it is recommended that indwelling time should be kept to a minimum, up to half a day at the most (Sekido et al., 2020). For this reason, proper patient education, including the fact that it is not an alternative to CIC, is essential.

FIG. 2 Specialized indwelling catheter for intermittent (temporary) use approved in Japan. To inflate and indwell the balloon in bladder, sterile water from the reservoir to the balloon is sent. To contract the balloon and remove the catheter, the sterile water in the balloon is sent back to the reservoir. DIB Cap is used for intermittent drainage, especially away from home. Kindly provided by courtesy of DIB International Co., Ltd., Tokyo, JAPAN.

Pharmacological treatment

To facilitate urine storage

Anti-cholinergic drugs, β3-adrenoceptor agonist, or a combination of these drugs suppresses DO and increases bladder compliance and bladder capacity, which ameliorates bladder storage dysfunction (Han, Cho, Jung, Jang, & Lee, 2019; Sekido et al., 2020; Stothers, Tsang, Nigro, Lazare, & Macnab, 2016). Therefore, these drugs are recommended for patients who have the risk factors for renal impairment and symptomatic UTI or UI (Sekido et al., 2020).

To facilitate bladder emptying

α1-Adrenernoceptor antagonists may reduce the resistance at the bladder outlet (Yasuda, Yamanishi, Kawabe, Ohshima, & Morita, 1996). Therefore, these drugs may be used in patients managed by (voluntary) voiding for their potential to improve voiding efficiency despite the lack of robust evidence of these drugs.

The use of parasympathomimetic drugs [muscarinic receptor agonists (e.g., bethanechol) and peripheral cholinesterase inhibitors (e.g., distigmine)] that may improve bladder contractility are not recommended because there is a dearth of evidence on these drugs for patients with NLUTD due to SCI and a possibility of worsening of functional BOO (Barendrecht, Oelke, Laguma, & Michel, 2007).

Assessment of clinical outcomes (periodic follow-up)

Proposal for follow-up protocol

Periodic follow-up is needed to ensure that clinical outcomes are achieved; it includes a medical interview and urinalysis every 3 to 6 months, combined with FVC or the bladder diary especially in patients with CIC, and transabdominal ultrasonography to evaluate the urinary tract annually (Kreydin et al., 2018; Sekido et al., 2020). Follow-up protocols of measurement of PVR and uroflow, and VUDS have not been established; however, these examinations should be performed within 3 to 6 months if urinary management and/or pharmacological treatments are changed. Moreover, these examinations should be promptly performed if urinary tract complications develop, UI is worsened, PVR increases, or bladder deformity becomes evident (Kreydin et al., 2018; Sekido et al., 2020). VUDS can tailor urodynamic study without fluoroscopy to the individual patient's condition.

Proposal for repeated urodynamic study

Regarding urodynamic study, The International Continence Society Urodynamic Committee proposed that "The panel recommends performing the first exam as soon as possible after the end of spinal shock phase and to perform another urodynamic testing at 6 and 12 months after the injury (level of evidence 4, expert opinions). Then, a yearly exam is preferable in SCI patients with cervical and thoracic injury for the first 5 years, deferring it to one in 2 years after attaining a low-pressure reservoir with continence and complete emptying. In case of lumbar injury, urodynamics could be done yearly for the first 2 years and once in 2 years thereafter (level of evidence 4, expert opinions)" (Schurch et al., 2018). In addition, the Committee emphasized that "Maximal attention should be paid to patients with incomplete suppression of detrusor overactivity, in those who empty their bladders by reflex voiding, to poor bladder compliance and in the presence of detrusor sphincter dyssynergia" (Schurch et al., 2018).

Proposal for surveillance for bladder cancer

Although the development of bladder cancer associated with long-term indwelling catheterization is a serious problem, recent reports suggest that the incidence of bladder cancer is not as high as previously thought (Elliott, 2015), and routine screening for bladder cancer using cystourethroscopy or urine cytology in asymptomatic patients is not recommended (Gui-Zhong & Li-Bo, 2017). On the other hand, it should be kept in mind that early detection of bladder cancer in patients with NLUTD is difficult and cancer-specific survival rates are low (Welk, McIntyre, Teasell, Potter, & Loh, 2013). Therefore, not only in patients under long-term indwelling catheterization, but also in all patients with NLUTD due to SCI, it is essential to try to investigate each case on an individual basis, without underestimating the suspicious signs of bladder cancer, such as gross hematuria, worsening of AD, refractory recurrent UTI, and abnormal thickening of the bladder wall on transabdominal ultrasound (Sekido et al., 2020).

Surgical treatment

Transurethral intra-detrusor injection of type A botulinum toxin (BoNT-A)

Several good quality randomized controlled trials have demonstrated the efficacy and safety of transurethral intra-detrusor injection of BoNT-A, thus establishing this minimally invasive treatment as an excellent option for refractory DO (Cruz et al., 2011; Ginsberg et al., 2012). BoNT-A hampers the fusion between a synaptic vesicle containing acetylcholine and a presynaptic membrane, leading to suppression of DO. BoNT-A decreases the number of UI episodes and detrusor pressure as well as increases bladder capacity and bladder compliance. The most frequent complications are symptomatic UTI and, in patients managed with voiding, increased PVR requiring CIC.

Other surgical treatments

The surgical therapies dealt with below should be performed by experienced neurourologists in the specialized centers for NLUTD. In addition, robot-assisted laparoscopic techniques for augmentation cystoplasty (AC), bladder neck surgery, and urinary diversion in patients with NLUTD are still considered to be in their infancy, but they show promise in terms of reducing the invasiveness of the procedures (Cohen, Pariser, Anderson, Pearce, & Gundeti, 2015; Gargollo, 2015).

AC

When all the maximum conservative and minimally invasive treatments fail, AC remains an important option for the improvement of progressive UUT deterioration, recurrent symptomatic UTI, and intractable UI that are attributed to refractory DO and low bladder compliance (Hoen et al., 2017). Usually, the bladder is augmented by a detubularized intestinal segment (enterocystoplasty) with the most commonly used segment being ileum (ileocystoplasty). The major problems with AC are the various frequently occurring peri- and postoperative complications. Peri-operative complications include prolonged ileus, wound infection, thromboembolism, and hemorrhage (Hoen et al., 2017). Long-term postoperative complications include urolithiasis, bowel dysfunction, electrolyte-metabolic disturbances, bladder perforation, and malignant neoplasm (Hoen et al., 2017). AC without the use of an intestinal segment is called auto-augmentation (detrusor myectomy), in which significant area of the detrusor is resected, leaving the mucosal layer intact. Although less invasive than enterocystoplasty, in terms of creating a low-pressure and high-volume environment for urine storage, auto-augmentation generally has poorer outcomes than enterocystoplasty (Wyndaele et al., 2018).

Anti-incontinence surgery

As surgical treatments for ISD in patients with NLUTD, bladder neck reconstruction (BNR), bladder neck sling (BNS), artificial urinary sphincter (AUS), and bladder neck closure with an abdominal continent catheterizable channel have been reported, although optimal surgical procedures remain controversial (Myers et al., 2016; Phé et al., 2017; Wyndaele et al., 2018). BNR is often selected for ISD associated with congenital anomalies, such as bladder exstrophy, and there have been few reports on the efficacy and safety for ISD associated with SCI (Myers et al., 2016). BNS can be conducted in both male and female patients, but the majority of reports are of a pubovaginal sling in female patients with some established efficacy and safety (Myers et al., 2016; Wyndaele et al., 2018). Not only in female patients but also in male patients with NLUTD, AUS is preferably placed at the bladder neck to probable decrease erosion rates (Myers et al., 2016; Wyndaele et al., 2018). Bladder neck closure is the last resort in cases of intractable UI resulting from severe ISD that would be difficult to treat with other anti-incontinence procedures, or in cases where previous anti-incontinence procedures have failed (Wyndaele et al., 2018). Moreover, mid-urethral synthetic sling procedures such as tension-free vaginal tape and transobturator tape in female patients as well as a perineal mesh sling in male patients with NLUTD have recently been reported (El-Azab & El-Nashar, 2015; Myers et al., 2016; Pannek & Wöllner, 2017). The postoperative complications include persistent UI, difficulty in catheterization, urolithiasis, device malfunction and device infection in AUS, vesico-cutaneous fistula and stomal stenosis in bladder neck closure with an abdominal continent catheterizable channel, and tape or mesh erosion in procedures using synthetic materials (Wyndaele et al., 2018).

Urinary diversion

Incontinent urinary diversion as well as a continent urinary reservoir is regarded as the last resort for carefully selected patients with NLUTD (Sekido et al., 2020). Although preservation of renal function, decreased incidence of symptomatic UTI, and attainment of social continence are achieved, a variety of peri- and postoperative complications may be encountered, which needs to be appropriately addressed (Sekido et al., 2020).

Sacral neuromodulation (SNM)

SNM may be a treatment of choice for carefully selected patients with incomplete SCI with refractory overactive bladder as well as nonobstructive urinary retention (Kessler et al., 2010). Electrode(s) for stimulation are usually inserted into the S3 foramen unilaterally or bilaterally, and stimulation to somatic afferents may bring reorganization of neural pathways to the central nervous system, resulting in suppression as well as enhancement of the micturition reflex. Moreover, recent studies indicated that implementing SNM during the acute phase of SCI above T12 may inhibit development of DO and DSD in the chronic phase (Sievert et al., 2010). Adverse events include new pain/undesirable change in stimulation, pain at the implantable pulse generator site, and adverse change in bowel function (Kessler et al., 2010).

Sacral anterior root stimulation (SARS)

SARS with dorsal rhizotomy may be a treatment of choice to attain voiding and urinary continence in extremely carefully selected patients with supra-sacral NLUTD due to complete SCI (Wyndaele et al., 2018). Although stimulation of S2 to S4 anterior roots excites both detrusor and the external urethral sphincter, once the stimulation is turned off, the external sphincter relaxes, while detrusor contraction continues, which means that voiding occurs after stimulation (poststimulus voiding). SARS not only reestablishes voiding, but also ameliorates UI, decreases the frequency of symptomatic UTI and AD, and prevents UUT deterioration through inhibition of DO due to dorsal rhizotomy (Wyndaele et al., 2018). Adverse events include device malfunction and leakage of cerebrospinal fluid (Wyndaele et al., 2018).

Transurethral sphincterotomy and others

As mentioned in "Urinary management" section, sphincterotomy for DSD is often performed to improve voiding efficiency and to prevent UUT deterioration in patients managed by bladder reflex triggering. Complications include insufficient relief of DSD leading to repeated procedures, hemorrhage, and urethrocutaneous fistula (Sekido et al., 2020; Wyndaele et al., 2018). Less invasive procedures such as urethral stents and intra-sphincteric injection of type A botulinum toxin, which is an off-label use, have been reported (Chancellor et al., 1999; Mehta et al., 2012), but have not become widespread yet.

Applications to other areas of neuroscience

Management for NLUTD due to spinal cord injury is the basis for all NLUTDs or non-NLUTDs (Groen et al., 2016). In terms of urinary management, CIC become the standard urinary tract management for NLUTD in which voluntary voiding is not urodynamically safe. For pharmacological treatment, anti-cholinergics and β3 adrenoreceptor agonists are used to ameliorate the neurogenic overactive bladder associated with stroke and Parkinson's disease. BoNT-A has established efficacy and safety in the treatment of refractory DO due to multiple sclerosis (Cruz et al., 2011; Ginsberg et al., 2012).

Moreover, a plenty of basic research using the SCI model has played a major role in elucidating the nervous system involved in LUT function. In normal animals, myelinated A-delta afferent fibers activate the micturition reflex, whereas in chronic SCI animals, micturition is induced by unmyelinated C afferent fibers, resulting in development of DO (de Groat et al., 2015). This contrasts with the pathophysiology of supra-spinal DO seen in stroke and Parkinson's disease, which is caused by loss of forebrain inhibition and/or enhancement of forebrain activation to PAG and PMC (de Groat et al., 2015). Recently, it was reported that transurethral intra-detrusor injection of BoNT-A reduced transient receptor potential vanilloid receptor 1 receptors and purinergic subtype 2X receptors on C fibers, which is considered to be a contributing factor for ameliorating DO (de Groat et al., 2015).

Mini-dictionary of terms

Bladder compliance: An index of the distensibility of the bladder during the storage phase. The normal bladder has very good distensibility, ensuring urine storage at low pressure and of sufficient capacity.

Detrusor: Smooth muscle of the bladder, which relaxes during the storage phase but contracts during the emptying phase.

Detrusor leak point pressure: The lowest detrusor pressure at leakage without detrusor contraction or increased abdominal pressure.

Detrusor overactivity: Involuntary detrusor contraction during the storage phase, which can be phasic or sustained.

Detrusor sphincter dyssynergia: Involuntary external urethral sphincter contraction concomitant with detrusor overactivity during the storage phase or voiding detrusor contraction during the emptying phase in patients with relevant neurological disorders.

Detrusor underactivity: Inadequate detrusor contractile strength and/or duration.

Frequency volume chart: A chart describing the time and volume of each micturition by voiding or clean intermittent catheterization. If relevant information such as the fluid intake, frequency and degree of, and circumstances at urinary incontinence, is also included, the chart is called a "Bladder diary."

Intrinsic sphincter deficiency: Incompetent urethral closure mechanism, which usually caused by anatomical or functional abnormality of the urethral smooth muscle and/or external urethral sphincter.

Neurogenic lower urinary tract dysfunction: Lower urinary tract dysfunction caused by relevant neurological disorders.

Nonrelaxing urethral sphincter: During the emptying phase, the external urethral sphincter is not relaxed but obstructed, resulting in reduced urinary flow.

Postvoid residual: Urine volume left in the bladder after voiding.

Urodynamic study: Examination for precise assessment of lower urinary tract function during storage and emptying, which simultaneously measures intravesical and abdominal pressure, infused volume of fluid, and often electromyography of external urethral sphincter, concomitant with uroflowmetry during the emptying phase. Detrusor pressure is calculated by subtracting abdominal pressure from intravesical pressure.

Uroflowmetry: Measurement of urine volume (mL) excreted per unit of time (s) using a specific device called a uroflowmeter.

Video-urodynamic study: Performing a urodynamic study under fluoroscopy, which enables functional as well as morphological evaluation.

Key facts of catheters for clean intermittent catheterization

Catheter for clean intermittent catheterization (CIC) is divided into two types: disposable and reusable.

The disposable catheter is popular worldwide and is divided into two types: polyvinyl (PVC) and hydrophilic-coated (HCC), although disposable catheters are frequently reused.

At CIC, PVC requires a lubricant for smooth catheterization, while HCC does not, which increases patient convenience.

HCC decreases the incidence of urinary tract infection and gross hematuria (surrogate for urethral trauma), improves the quality of life, and is cost-effective, although long-term outcomes remain controversial.

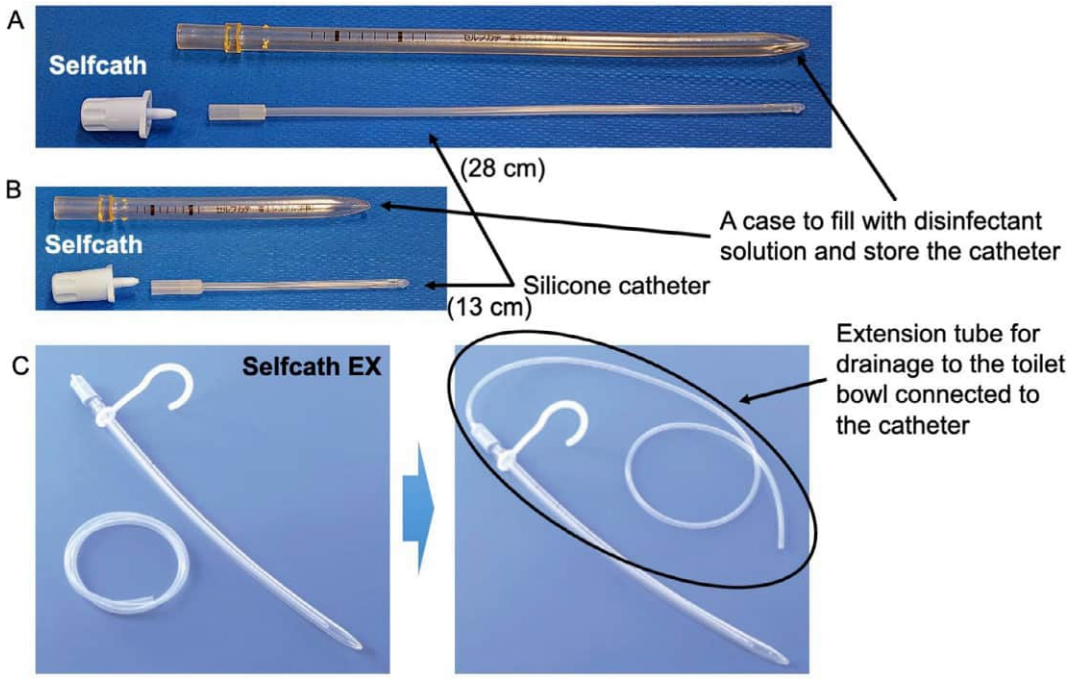

FIG. 3 Examples of reusable silicone catheters approved in Japan. The patients carry the reusable silicone catheter in a case filled with disinfectant solution. (A) for males; (B) for females; (C) for wheelchair patients. Kindly provided by courtesy of Fuji Systems Corporation, Tokyo, Japan.

The cost of HCC is an obstacle to its widespread use, especially in developing countries.

Disposable catheter waste may become an issue in the future in terms of environmental impact.

A reusable catheter is available in some countries, for example in Japan, and some patients use a reusable catheter at home, while using a disposable catheter away from home.

In Japan, several kinds of reusable silicon catheters (Fig. 3) have been approved and widely used for many years, but they should be changed monthly according to the product description, and is stored in a glycerine solution containing 0.025% benzalkonium chloride that is changed daily.

Some reusable catheters are designed to be more convenient for wheelchair patients (Fig. 3).

Summary points

- Management of lower urinary tract dysfunction is an important part of the clinical practice of patients with spinal cord injury.
- The critical clinical outcomes to be achieved are prevention of urinary tract complications, especially renal impairment and symptomatic urinary tract infection, attainment of social urinary continence, and improvement of quality of life.
- Video-urodynamic study plays an important role in identifying risk factors for renal impairment, symptomatic urinary tract infection, and urinary incontinence.
- Appropriate urinary management and pharmacological treatment aimed at preventing renal impairment and symptomatic urinary tract infection are determined depending on the presence or absence of risk factors for these urinary tract complications.
- If these outcomes are achieved, urinary management and pharmacological treatment to obtain social urinary continence and enhance the quality of life should be optimized without compromising the outcomes of prevention of renal impairment and symptomatic urinary tract infection.
- If maximum conservative treatment fails to achieve the above outcomes, surgical treatment becomes an option.

NPIAP	National pressure injury advisory panel
PI	Pressure injury
SCI	Spinal cord injury

Introduction

After a spinal cord injury (SCI), individuals often remain with limitations that will impede mobility and functional independence. Presence and severity of the neurological deficits associated with SCI represent important risks for developing pressure injuries (PI). During hospitalization, pain, associated injuries, medical complications, spasticity, joint contractures, and surgical interventions may further lead to prolonged bed rest and contribute to increased occurrence of PI. Achieving an optimal plan for preventing PI can be difficult in practice, particularly for individuals requiring total assistance for mobilization and repositioning in bed. The selection of a specialized support surface is thus a critical component of a comprehensive plan for PI prevention and treatment. Support surface refers to "a specialized device for pressure redistribution designed for management of tissue loads, micro-climate, and/or other therapeutic functions" as defined by the National Pressure Injury Advisory Panel (NPIAP S31, 2007). In this document, support surface pertains to bed, mattress, overlay, and integrated bed system. At the end of this chapter, the reader will be able to:

(1) Describe the different forces that are involved in the pathogenesis of PI in the SCI population.
(2) Provide an overview of the main types and features of support surfaces to prevent and/or treat PI.
(3) Propose a simple decision table for guiding healthcare providers to select a support surface for the prevention and treatment of PI in hospitalized SCI patients.

Pressure injuries (PI): Definition, epidemiology and impacts

Defined by the National Pressure Injury Advisory Panel (NPIAP) as a "localized damage to the skin and/or underlying tissue over a bony prominence," pressure injuries (PI) (also called bedsores, decubitus ulcers, pressure sores) represent one of the most common medical complications experienced by hospitalized patients (NPIAP, 2021). No other preventable event occurs as frequently as PI, occurring at a rate of 2%–40% of all acute care hospitalization in the United States and Canada (NPIAP, 2021; Cullum, McInnes, Bell-Syer, & Legood, 2004). PI can occur throughout the continuum of care, with a prevalence of 9.7%, 11.8%, and 12.0% for all patients hospitalized in acute care, in patient rehabilitation, and long-term care (nursing home), respectively (NPIAP, 2021).

In the lying position, PIs usually develop at the sacrum (17%–27%), heel (9%–18%), malleoli (4.6%), trochanters (1.4%), and scapulae or occiput (<5%) areas (Bhattacharya & Mishra, 2015; Kruger, Pires, Ngann, Sterling, & Rubayi, 2013; Talley Group, 2021). It is however proposed that prevention and management of heel PIs may be best managed independently from the bed support surface (Norton, Coutts, & Sibbald, 2011). The occurrence of PI is

Diagnosis and Treatment of Spinal Cord Injury. https://doi.org/10.1016/B978-0-12-822498-4.00022-1

particularly concerning for individuals with SCI as it interferes with rehabilitative care, community reintegration, and quality of life (Consortium for Spinal Cord Medicine, 2014; Cullum et al., 2004; McInnes et al., 2015). PIs are associated with higher morbidity and mortality and represent an enormous growing financial burden for healthcare systems, with a patient care cost per PI of 20,900 US$ to 151,700 US$, totalizing 26.8 billion US$ in 2019 (Chan et al., 2013; NPIAP, 2021). Individuals with SCI are among the most vulnerable populations for PI, occurring in more than 95% of them during their lifetime (Cowan et al., 2019). Recent literature estimates that hospital-acquired PI among SCI patients ranges from 29.7% to 49.2% (Tran, McLaughlin, Li, & Philips, 2016). According to Fuhrer, Garber, Rintala, Clearman, and Hart (1993), the risk to develop PI is higher for individuals with severe spinal cord injury.

Pathogenesis of pressure injuries following spinal cord injury

The pathophysiology of PI involves different extrinsic factors, paralleling the severity of the neurological impairments related to the SCI. Pressure is acknowledged to be the main factor and is defined as the amount of force applied *perpendicular* to a surface per unit area of application (International Review, 2010). In addition, shearing and friction represent stresses that are exerted *parallel* to the area of application and significantly contribute to the capillary damage (Agrawal & Chauhan, 2012; International Review, 2010) (Fig. 1). The resultant reduction in blood flow reduces the oxygen and nutrients being delivered to the tissues, while simultaneously limiting the removal of metabolic waste products (Agrawal & Chauhan, 2012; Bhattacharya & Mishra, 2015). Neurological impairments associated with severe SCI also lead to difficulties in identifying painful stimulus associated with prolonged and/or excessive compression, to which must be added the difficulty to make independent postural adjustments necessary to restore tissue perfusion (Bhattacharya & Mishra, 2015; Grey & Harding, 2006). Without the relief of compression on soft tissues, ischemia persisting for more than 2 hours may lead to necrosis of subcutaneous tissues (Kuffler, 2015). Inadequate maneuvers while transferring, repositioning, and positioning in bed may also lead to excessive shearing and friction stresses to the skin, further contributing to the development of PI (Agrawal & Chauhan, 2012). Immobility is also associated with the build-up of temperature at the interface, increasing local inflammation biomarkers, associated with PI occurrence (Yoshimura et al., 2015).

Dysfunction of the autonomic nervous system may also contribute the pathophysiology of PI following SCI, by altering the micro-vascular response below the level of the injury. Blood flow regulation relies on the rhythmic alteration of blood vessels constriction controlled by central neurogenic, local myogenic and metabolic mechanisms, which can be altered following SCI (Brienza, Geyer, & Jan, 2005). Impaired myogenic and neurogenic responses of the vascular smooth muscle due to chronic denervation also lead to an inappropriate local blood flow and metabolic responses to pressure load and unload. This phenomenon may be exacerbated in individuals with endothelial dysfunction (for instance, caused by smoking) and in the elderly, for which the loss of elastin and degradation of the collagen matrix put the skin at further risk of deformation of the blood vessels under loading pressure (Phillips, Ainslie, Krassioukov, & Warburton, 2013).

Moreover, 70%–84% of individuals with SCI experience sphincter dysfunction (neurogenic bladder & bowel), which may lead to higher moisture and irritation of the skin, fostering the development of PI (Agrawal & Chauhan, 2012). Nutrition status, comorbidities and body weight should also be assessed following SCI. Obesity and diabetes may reduce the skin ability to dissipate local heat and cutaneous temperature regulation under loading. On the other hand, muscle atrophy associated with SCI may make bony prominences to emerge, leading to increased local pressure and friction/shear in bed. Spasms and joint contractures associated with SCI should also be assessed, as a potential cause of excessive friction and shear and hindrance for proper positioning and repositioning in bed (increased pressure).

Support surfaces: An approach for prevention and treatment of pressure injuries

Biomechanical properties of support surfaces during loading

Support surfaces use three main mechanisms to prevent PI during loading: (1) pressure redistribution; (2) micro-climate, and (3) horizontal stiffness management. Their performance levels on these important features allow differentiating between the variety of available products and help in selecting a proper support surface that matches patient's needs. During loading, the pressure at a specific location will decrease as the contact area increases. Based on this concept, support surfaces aim to redistribute the pressure by using two basic principles (Consortium for Spinal Cord Medicine, 2014; International Review, 2010; McInnes et al., 2015; NPIAP, 2021) (Fig. 2):

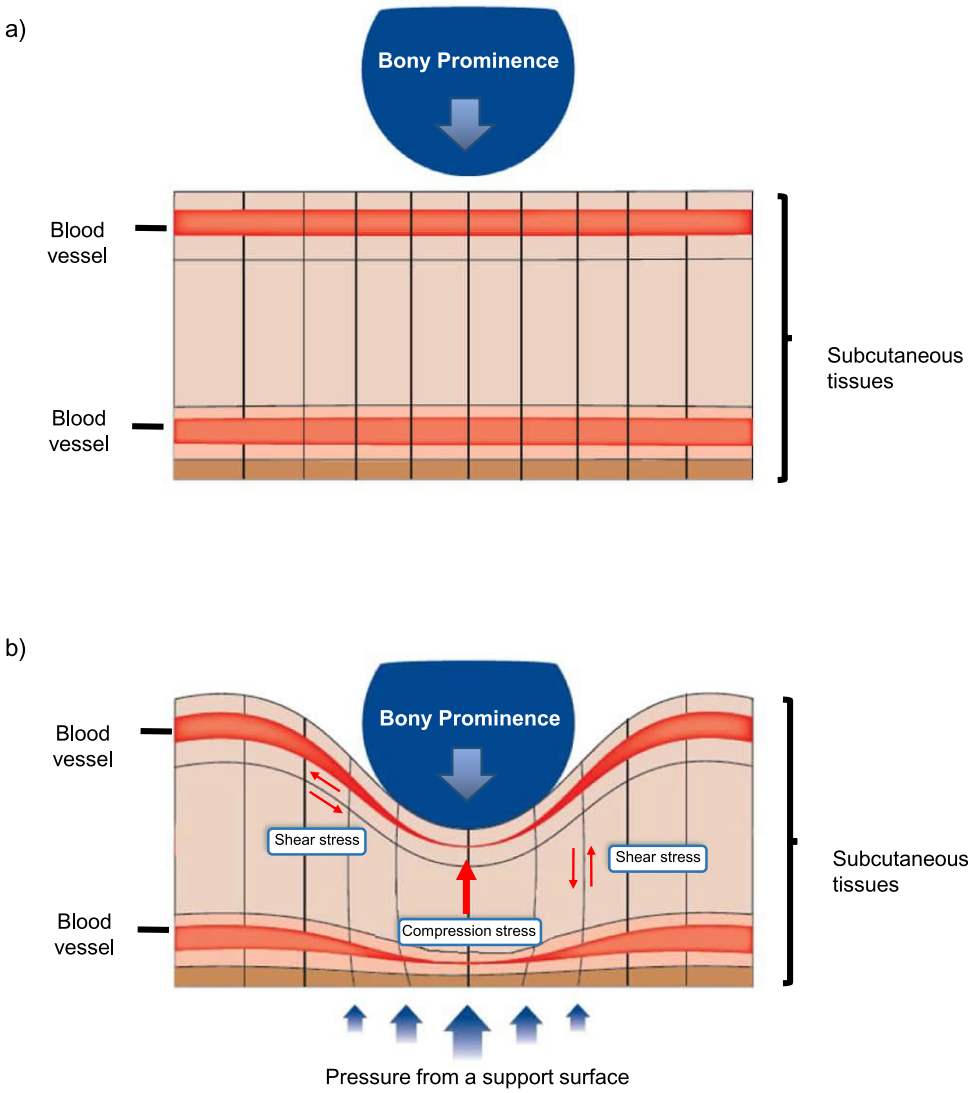

FIG. 1 Compression and shear stresses resulting from an even pressure distribution. (A) Forces applied by the bony prominences, (B) exerted compression and shear stress to subcutaneous tissues that contribute to their damage. *(Adapted from Wounds International (Pressure ulcer prevention: pressure, shear, friction, and micro-climate in context. A consensus document.))*

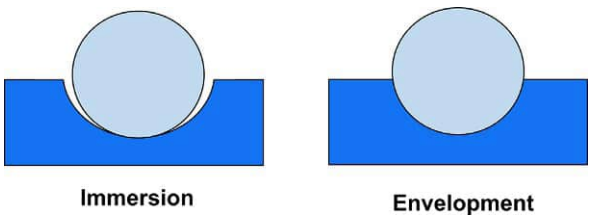

FIG. 2 Illustration of pressure mode distribution. This figure illustrates the ability of a support surface to let the body sink (immersion) or mold its contour (envelopment) to redistribute pressure.

(1) *Envelopment*, referring to the ability of a support surface to conform, so to fit and mold around irregularities in the body. It is generally measured in laboratories by indenter tests providing average pressures on each depth level (mm Hg).
(2) *Immersion*, referring to the penetration (sinking) of the body into a support surface, measured by the depth of penetration (mm).

A higher envelopment and immersion performance of a support surface is associated with greater pressure redistribution, but at the expense of higher instability of the surface making it more difficult for a patient to reposition and/or get out of bed (NPIAP, 2021).

The *micro-climate* is defined as the temperature and humidity at the body interface with the support surface and plays an important role in the development of PI, independently of the average peak pressure (Yoshimura et al., 2015). High skin temperature leads to an increased cutaneous stiffness under loading, higher inflammation, and metabolic activity, further leading to tissue damage (Reger, Adams, Maklebust, & Sahgal, 2001). Moisture can accumulate on the skin increasing the coefficient of friction at the interface while diluting the skin acidity, which was shown to reduce its antibacterial properties (Reger et al., 2001; Tomova-Simitchieva, Lichterfeld-Kottner, Blume-Peytavi, & Kottner, 2018). Micro-climate is measured in laboratories using the local temperature, relative humidity, evaporative capacity and/or dissipating properties of the support surface. However, support surfaces that provide great micro-climate management may also cause patients to feel cold or dehydrate.

The *horizontal stiffness* refers to shear and friction stresses that are generated when the gravity pulls the body down on a support surface, which reacts by pushing back. Horizontal stiffness is measured and reported in Newtons of force. A stiff support surface exerts high resisting forces on the tissues in response to a given amount of displacement, while this force is lower for softer support surfaces. However, the latter can contribute to sliding down in the bed and even to falls (NPIAP, 2021).

Main configurations and classification of support surfaces

Support surfaces are commercially available in three main configurations: (1) mattress, (2) mattress overlay (on top of the patient's mattress), and (3) integrated bed system (combining bed frame and a support surface into a single unit). Individuals with SCI with limited mobility may particularly benefit from specialized bedframes (manual, semi-electric, and electric), which allow adjustments of height and head/foot elevation. These adjustments may promote functional independence, enhance sleep quality, and manage different medical conditions associated with SCI (e.g., autonomic dysreflexia, orthostatic hypotension, and/or spasticity).

Support surfaces can be classified into two main groups (reactive or active) based on the technology used (Hougton et al., 2013; International Review, 2010). Costs related to the different types of support surface technologies are important to consider, as the most expensive does not necessarily signify the "best" mattress for a given patient. Specific properties and performances should be analyzed based on a holistic assessment of the patient's characteristics.

Reactive support surfaces

Reactive support surfaces are powered or non-powered surfaces with the ability to adjust its load distribution properties solely in response to an applied load (Hougton et al., 2013; NPIAP, 2021). Thus, reactive support surfaces do not independently change its load distribution. Consequently, reactive support surfaces provide a constant pressure at the interface, unless the patient actually moves. Different types of reactive support surfaces are available, differing by their structure and material used, providing different properties.

Non-powered reactive support surface

Foam

In its simplest form, a non-powered reactive support surface consists of a single block of foam covered by a plastic or nylon cover. Foam has a flexible, cellular material structure, which may be available in different densities. Foam mattress work reactively to provide pressure redistribution by spreading the load across the whole interface surface area (NPIAP, 2021). However, their capacity to immerse and envelop the body is limited by their stiffness and density (Hougton et al., 2013). Due to its low cost, foam mattresses are widely used in hospitals (Berthe, Bustillo, Mélot, & de Fontaine, 2007). Within this type of support surface, high specification foam may incorporate multiple constructs and/or be compartmentalized into different sections with distinct properties (Hougton et al., 2013; International Review, 2010; NPIAP, 2021). Softer foam mattresses will provide higher level of immersion as compared to stiffer foams, but necessarily need to be thick enough to avoid "bottoming out," referring to the deformation beyond critical immersion whereby the effective pressure redistribution is lost (International Review, 2010; NPIAP, 2021). Foam mattresses can progressively degrade and lose their capability of returning to its original forms or thickness, typically wearing out after 3 years (Brienza et al., 2005; Consortium for Spinal Cord Medicine, 2014). Cullum et al. (2004) suggested that high specification foam mattresses were more effective than

"standard" hospital foam mattresses in moderate to high-risk patients in terms of pressure relief. Bueno de Camargo et al. (2018) suggested that the use of a viscoelastic support surface reduced the incidence of PI (stage 2) in critically ill patients when compared to standard mattress. Moreover, when non-air reactive mattresses are used, the use of contoured postural management components may enhance its pressure redistribution properties (Hosking, 2017).

Gel

Gel mattresses consist of a semi-solid system of solid aggregates, colloidal dispersion or polymers exhibiting elastic properties (NPIAP, 2021). Gel mattresses can range from hard to soft, providing distinctive immersion, envelopment, and horizontal properties. Gel mattresses are generally easy to clean up; however, they may be heavy. Temperature and moisture control may be challenging with the use of non-air non-powered reactive support surfaces, due to their lack of aeration and poor heat conduction properties (Brienza et al., 2005). Tomova-Simitcheva et al. showed in 2017 that a reactive gel support surface (featuring a breathable cover and an open gel column) may exhibit similar effectiveness with an alternating pressure mattress (with low-air-loss function) on the transepidermal water loss, temperature, and erythema at the sacral and heel skin, both being superior as compared to a basic foam mattress.

Air-filled

The use of reactive air-filled mattress overlay is an alternative in patients at some risk of PI development. Indeed, Conner and Clack (1993) suggested that air mattress overlay plus three-inch foam increases its area of contact and reduced tissue shear when compared with foam overlays, using in vivo measurements derived from pelvic CT scans. Matsuo et al. (2011) demonstrated that in air support surfaces, the internal pressure adjustment (inflation level) significantly influenced pressure redistribution properties, with a lower internal pressure resulting in greater immersion and contact area, resulting in a decreased maximum interface pressure. Similarly, Higer and James (2016) demonstrated that the reactive air support surface was the most effective pressure-redistributing material for pediatric occipital pressure, displaying the lowest interface pressure and the most homogeneous pressure distribution compared to foam, fluidized and gel surfaces.

Powered reactive support surface

In a more complex form, reactive support surfaces use a powered flow of air to assist in the management of temperature and humidity of the skin (NPIAP, 2021). Low-air-loss support surfaces are composed of multiple air chambers throughout. However, in contrast to alternating air pressure support (discussed below), low-air-loss surface displays tiny holes at its top surface continually blowing air out, while maintaining a specific inflation level in the chambers (Fig. 3) (Brienza et al., 2005; Hougton et al., 2013; International Review, 2010; McInnes et al., 2015). The pressure at which the support surface must be inflated, and the rate for blowing out the air, is based on the individual's height and weight (Brienza et al.,

High / Active Technologies	Mechanism of action	Effect on properties during loading
Alternating air pressure		- Pressure redistribution via powered cyclic changes in loading and unloading characterized by specific parameters - Immersion and envelopment
Low-air-loss		- Immersion and envelopment - Microclimate management
Air fluidized		- Immersion and envelopment - Microclimate management

FIG. 3 Description of active support surface technologies. This figure aims to summarize the active technologies and illustrates their mechanisms of action. *PR*, pressure redistribution; *SR*, shear reduction; *MC*, microclimate management; *T*, impact on self-transferring ability. *(Adapted from Wounds International (Pressure ulcer prevention: pressure, shear, friction and microclimate in context. A consensus document.))*

2005), and is adjusted to provide the desired level of immersion/envelopment. Temperature and moisture control at the skin surface is also improved, as compared to alternating air pressure system and non-powered support surfaces, most likely due to the evaporation effect caused by air circulating from the permeable cover (International Review, 2010; Reger et al., 2001). However, the optimal skin temperature and moisture level for PI prevention is still unknown, and this technology represents higher costs compared to non-powered systems (Reger et al., 2001).

A comparison cohort study by Black et al. in 2012 has suggested that critically ill patients placed on low-air-loss mattresses with micro-climate management in surgical intensive care unit had lower PI (stage 2) incidence than those placed on an integrated power air pressure redistribution beds (air alternating pressure) (Black, Berke, & Urzendowski, 2012). Lippodolt et al. in 2014 showed that low-air-loss technology significantly reduced the interface pressure at 0, 10, 30, and 45 degrees of backrest elevation in comparison with foam and air suspension support surfaces (air fluidized). It was thus suggested that low-air-loss technology could be an additional useful tool to help prevent skin breakdown at the sacrum as a compromise between seemingly incompatible demands of skin integrity and prevention of ventilator-associated pneumonia (Lippoldt, Pernicka, & Staudiner, 2014). However, this study did not assess horizontal stiffness.

Reger et al. also suggested in 2001 that measurements of support interface climate change might allow for selective grouping of low-air-loss surfaces according to their rate of moisture evaporation and resulting temperature reduction. Combined, these characteristics can effectively describe the performance of any low-air-loss support system and may be used to define standards of performance (Reger et al., 2001). A meta-analysis completed by Shi, Dumville, and Cullum (2018) suggested that hybrid low-air-loss air surfaces may have the highest probability of being the most effective intervention for PI prevention. However, the authors remain uncertain as to the true ranking of the different support surfaces because the certainty of evidence was very low (Shi et al., 2018). It was also suggested that the performance of low-air-loss support surfaces may also be influenced by their age and should thus be assessed in the quality assessment of these technologies (Black et al., 2012).

Active support surfaces

In opposition to reactive support surfaces, active support surfaces are powered support surface that have the ability to periodically change the load distribution regardless of the applied load (individual's position or movement) (McInnes et al., 2015). This technology mostly rely on its ability to provide pressure redistribution via cyclic changes in loading and unloading as characterized by frequency, duration, amplitude and rate of change parameters (Cullum et al., 2004; McInnes et al., 2015; NPIAP, 2021). Because of this feature, powered support surfaces are generally beneficial to individuals with low mobility. Furthermore, the inflation level can be adjusted to provide the desired level of immersion/envelopment and horizontal stiffness with the body. As illustrated in Fig. 3, active support surfaces can be stratified into two groups according to their mechanism of action (alternating air pressure and air fluidized).

Alternating air pressure

Alternating air pressure support surfaces are composed of multiple air chambers throughout, in which the air is pumped alternately to inflate and deflate the chambers (Fig. 3) (Brienza et al., 2005; Consortium for Spinal Cord Medicine, 2014; Hougton et al., 2013; McInnes et al., 2015). As a result, the pressure is periodically relieved and redistributed by changing the location of the contact areas between the individual's body and the support surface (Brienza et al., 2005; Hougton et al., 2013; McInnes et al., 2015). Cyclic redistribution of loading helps to restore blood flow and re-establish blood supply to the soft tissues (Vanderwee, Grypdonck, & Defloor, 2007). However, it was recently hypothesized that unloading may be associated with reperfusion-induced inflammatory process (Xiao, Wu, & Mak, 2014). Accordingly, the main limitation of air alternating support surfaces remain the lack of evidence pertaining to the ideal frequency, duration and amplitude of cell's inflation/deflation for preventing and treating (Cullum et al., 2004; McInnes et al., 2015). However, a study by Rithalia and Gonsalkorale (1998) showed that the maximum contact pressure on the sacrum were significantly lower on devices for which inflation pressure was adjusted according to the body mass of the subject.

Hickerson, Slugocki, Thaker, Dunkan, and Bishop (2004) investigated the pressure-relieving ability of three specialized support surfaces (low-air-loss, air fluidized, pegasus airwave (air alternating pressure)) compared to a standard foam hospital mattress, by measuring the total body tissue interface pressure. The air alternating pressure surface outperformed the other tested support surfaces by decreasing the overall pressure (Hickerson et al., 2004). A meta-analysis completed by Shi et al. in 2018 suggested a moderate certainty evidence that powered active (alternating) air surfaces and powered hybrid air surfaces (offering both reactive and active pressure redistribution modes) probably reduce PI incidence compared with standard hospital surfaces by 58% and 78% on average, respectively.

An interesting study was completed by Jan, Brienza, Boninger, and Brenes (2011), aiming to guide the selection of parameters of commercial alternating pressure support surfaces for the prevention of PI in the SCI population. In this study, sacral skin response (using laser Doppler flowmetry) was compared for different pressure interface in alternating air pressure and continuous (reactive) air systems. Results showed that alternating pressure (at a low-interface pressure at 0 mmHg and high-interface pressure at 60 mmHg with a cycle time of 5 min) enhanced skin perfusion of weight bearing tissues as compared with constant pressure (with an interface pressure of 30 mmHg) in people with SCI.

Air fluidized

Air fluidized is a feature of a support surface that provides pressure redistribution by forcing air through a granular medium (e.g., beads) producing a fluid state (NPIAP, 2021; Reddy, Gill, & Rochon, 2006). This high-technology (also called high-air-loss) may provide the greatest level of immersion and envelopment of any support surfaces (Brienza et al., 2005; International Review, 2010; McInnes et al., 2015). According to Holzapfel (1993), almost two-third of the body is immersed using this type of support surface, which represents a large contact surface distribution (Holzapfel, 1993). In addition to its high-pressure redistribution quality, air fluidized support surfaces also provide an effective micro-climate management, by letting warm air escape from the top surface (Brienza et al., 2005; International Review, 2010). Rothenberg et al. examined in 2014 the heel blood flow between standard hospital foam mattress bed, viscoelastic foam mattress and an air-fluidized bed. Authors reported that only the air-fluidized bed resulted in a maintained blood circulation (Rothenberg et al., 2014). Previous randomized controlled studies have shown the benefit of this system for individuals with stage III and IV PI in comparison with other non-fluidized support surfaces (International Review, 2010). However, it also showed its risk of dehydration and dry skin (also indirectly associated with PI). One systematic review reported significant reductions in PI size (of any stage and any setting) with air-fluidized devices (McInnes, Jammali-Blasi, Bell-Syer, & Leung, 2018). Authors however concluded that there was a limited evidence for the effectiveness of air-fluidized as opposed to "low-tech" devices in the treatment of existing PI. While the body of evidence was qualified as "good" by Cullum, Deeks, Sheldon, Song, and Fletcher (2000), it was deemed as low quality by McInnes (McInnes et al., 2018). Air fluidized technology is also one of the most expensive support surface system.

Emerging technologies

Adjustable rotational beds consist in integrated bed systems featuring computerized lateral rotation (tilting) of the support surface for assisting patients for periodical repositioning in bed. In addition to promoting functional independence, these systems may also facilitate caregiver interventions (e.g., turning and transferring individuals, examining the skin, assisting in bedding equipment changes, and providing physical/respiratory therapies). Different tilting options can be provided, such as rotational beds and lateral rotating beds. On the other hand, these systems are expensive. Moreover, while pressure redistribution in this system mainly relies on the repositioning of the patient, these systems may potentially generate higher shear and friction stresses than conventional technologies. However, this remains to be defined in the clinical and laboratory settings.

Positioning, surface material and bed making

Positioning of the bed and surface materials are important factors to consider as they influence support surfaces performance during loading. A recent study by Boyle et al. (2020) identified, using a computational model of the weight-bearing pelvis that applying a sufficient supporting lateral pressure may counteract the under-body pressure. Although this study was completed in seated individuals, this strategy is yet to be determined in the lying position (support surfaces) (Boyle et al., 2020). Tran et al. in 2016 investigated the impact of the repositioning frequency on shear stress and overall healthcare cost by decreased utilization of medical personnel. The authors concluded that the traditional repositioning frequency of every 2 hours may be equal in effectiveness to a frequency of 4 hours, and it was suggested that the frequency of repositioning be individualized based on the patient's risk factors, needs and support surface utilized (Tran et al., 2016). Current literature doesn't show that any method of positioning is preferred, and therefore, 30-degree tilted side-lying position, the prone position, and the 30-degree semi-Fowler position, are all considered acceptable (Tran et al., 2016).

Current evidence suggests that surface material impacts on micro-climate, temperature, and humidity at the interface. Posada-Moreno et al. (2011) observed that temperatures were lower in all risk areas that had no support surface protector and were greater when the surfaces were in contact with protector material, with increases up to 2.13°C. Recent studies suggest that silk-like fabrics may be effective in reducing shear and subsequent PI when compared with cotton or cotton-

blend fabrics (Tran et al., 2016). Iuchi et al. (2014) showed that friction and bed making method do not significantly reduce maximum interface pressure, although the hammock effect (forces generated by tension along the loaded interface) can be reduced through the use of stretchable bed sheets on the support surface (Iuchi et al., 2014). Another study proposed by Williamson et al. (2013) concluded that putting additional linens or underpads on low-air-loss surfaces may adversely affect skin temperature and moisture, thereby reducing the PI prevention potential of these surfaces.

Global evidence on the effectiveness of support surfaces

Globally, studies assessing support surfaces are heterogeneous in terms of settings, participants' baseline skin status, and follow-up durations. Moreover, over half of the studies have serious or very serious study limitations, reflecting the global uncertainty of evidence pertaining to the efficacy of support surfaces technologies to prevent and treat PI. It was also reported that most studies assessing support surfaces in PI prevention mostly involved participants aged over 55 years old, suggesting that the current evidence may generally apply for the older population (Shi et al., 2018). Overall, with the current state of evidence, it is thus impossible to determine the most effective support surface for either prevention or treatment. Thorough assessment of the patient's characteristics is required for selecting a support surface that will best serve the patient's needs.

Decision-making for selecting proper support surfaces

Proper risk assessment and implementation of prevention strategies for PI are crucial to providing comprehensive care in the SCI population while reducing healthcare costs (Tran et al., 2016). The following section aims to propose a simple algorithm to identify an appropriate support surface for patients with SCI in hospital settings. This section considers recommendations of the S31 NPIAP committee for "using standards to choose wisely" (NPIAP, 2021), suggesting these important steps:

- *Carefully consider the patient population and needs*

  SCI individuals may be highly vulnerable to PI occurrence, according to their level and severity of the injury, which is particularly true in hospitals setting. Accordingly, particular attention should be given to the following characteristics at admission: presence and severity of motor and sensory function, risk of sphincter incontinence, current or past PI, presence of obesity or bony prominence(s), comorbidities, age, smoking status, and nutritional status. The current mobility (transfer and repositioning) and functional status are also crucial to assess. Secondary conditions related to the SCI and medical complications should also be identified, as they may limit proper positioning and/or repositioning of the patient in bed (orthostatic hypotension, dysphagia, mechanical ventilation, spasticity, joint contractures, etc.).

  Individuals with severe (motor-complete) tetraplegia (or high paraplegia) may be at risk of autonomic dysreflexia and poikilothermia (defined as the ability to regulate core body temperature due to the SCI), leading to variability of the body temperature and higher risk of elevated temperature/moisture. The authors thus recommend that the temperature of low-air-loss and air fluidized support surfaces be carefully monitored in individuals with SCI at risk of poikilothermia. Finally, as suggested by Norton et al. (2011), heels will be excluded of the proposed decision table, as the prevention and management of PI at this location may be best managed independently from the support surface.
- *Determine the type of support surface that will be evaluated and request relevant testing data for the chosen surface from manufacturers*

  After determining the patient's profile and needs, selection of the support surface's type can be completed by matching their specific properties (ability of immersion, envelopment, horizontal stiffness, and to manage microclimate) during loading. Table 1 (adapted from Norton et al., 2011) provides a simple decision table to guide the multi-disciplinary team to select a support surface's type based on relevant characteristics of the SCI population in a hospital context (for prevention or treatment of PI). One can also refer to the manufacturer's data and current literature to compile support surface's performance characteristics on pressure redistribution and micro-climate properties to provide an overall ranking for the most appropriate support surface type, considering costs and hospital resources. Finally, collaborate with the hospital's administration regarding procurement of recommended support surface, keeping in mind that PIs are a common and resource-intensive challenge for hospitals worldwide and prevention strategies are significantly less costly than treatment regimen.

TABLE 1 Decision table for selecting an appropriate support surface type in the SCI population based on the patient's mobility level in bed (vertically) and important risk factors of PI development during hospitalization (horizontally).

		PI risk assessment (sphincter incontinence, level and severity of sensory and motor dysfunction, etc.)			
		Prevention		Treatment	
		No other risk factors No PI	Other risk factors + No PI	PI +	Severe/refractory/ multiple PI or cannot be positioned off
Ability to change position in bed	Total assist	Non-powered reactive or active (APA)	Active (APA)	Powered reactive or active (APA)	Powered reactive or active (AF to consider)
	Moderate assist	Non-powered reactive	Reactive or active (APA)	Powered reactive or active (APA)	Powered reactive or active (AF to consider)
	Independent with or without device	Regular hospital mattress[a]	Non-powered reactive	Reactive	Powered reactive or active (AF to consider)

[a]*Only category where standard hospital mattress may be acceptable.*
This table serves as a guidance to the multi-disciplinary team with experience in SCI care *to select a support surface's type based on relevant characteristics of the SCI population in a hospital context for prevention or treatment of PI.* PI*, pressure injury;* APA*, air pressure alternating;* AF*, air fluidized; Powered reactive (low-air-loss feature); Non-powered reactive (gel, air-filled).*

Conclusion

Despite advances in the prevention and management of pressure injury (PI) in the last years, PIs remain a severe and frequent medical complication associated to SCI. Support surface is a critical part of the comprehensive plan for the prevention and treatment of PI. Various types of support surfaces have emerged over the years, this chapter aimed at providing information to guide healthcare professionals in selecting an appropriate support surface based on the patient's characteristics and needs following a spinal cord injury (SCI) in hospital settings.

Applications to other areas of neuroscience

Pressure injuries (PI) are preventable medical complications involving all populations with limited mobility and/or independence. Individuals with spinal cord injury (SCI) represent one of the most vulnerable populations for PI throughout the continuum of care and particularly during hospitalization. Similarly, individuals affected by any neurological condition (e.g., traumatic brain injury, stroke, neurocognitive disorder, etc.) affecting their mobility will have an increased risk of developing PI. The level of mobility, neurological status, comorbidities, history of PI and multiple other factors (such as the presence of humidity due to bladder/bowel dysfunction and nutrition level) are important to consider when assessing patient's risk factors of PI. Selection of an appropriate support surface is one of the cornerstones of the comprehensive plan for the prevention and treatment of PI. In this chapter, we have reviewed the epidemiology and pathogenesis of pressure injury as well as its global impact for the spinal cord injury population, particularly in the hospital context. The effects of support surfaces on skin properties (envelopment, immersion, horizontal stiffness and micro-climate management) during loading were also discussed. The main configuration and classification of support surfaces (types, technologies and features) were described and discussed in a clinical context, based on the current clinical and biomechanical studies. Specific characteristics, limitations, and effectiveness of each support surface are also presented. Strategies in the positioning, repositioning in bed, surface material and bed making were also discussed as they may influence the support surface's properties. Along with providing an overview of the main types and features of support surfaces available for the prevention and treatment of PI, this chapter proposes a simple and comprehensive algorithm for the selection an appropriate support surface for the prevention and treatment of PI specific to the SCI population in a clinical context.

Mini-dictionary of terms

The following terms and definitions are provided based on the National Pressure Injury Advisory Panel Support Surface Initiation (S31) "Terms and definitions related to support surfaces" Ver. 01/29/2007, revised 12/27/2018; 11/19/2019. Retrieved at: https://npiap.com/page/S3I.

Active support surface: A powered support surface, with the capability to change its load distribution properties, with or without applied load.
Mechanical load: Force distribution acting on a surface.
Pressure redistribution: The ability of a support surface to distribute load over the contact areas of the human body.
Reactive support surface: A powered or non-powered support surface with the capability to change its load distribution properties only in response to applied load.
Support surface: A specialized device for pressure redistribution designed for management of tissue loads, microclimate, and/or other therapeutic functions. Support surfaces include but are not limited to mattresses, integrated bed systems, mattress replacements or overlays, or seat cushions and seat cushion overlays.

Key facts of pressure injuries after spinal cord injury

- Individuals with spinal cord injuries represent a population highly vulnerable for pressure injuries, which represent one of the leading causes for unplanned re-hospitalizations (Chen, Devivo, & Jackson, 2005).
- Although pressure injuries are evitable, they represent a major public health problem, as their occurrence is associated with severe comorbidities and enormous costs of care (as much as 25% of the total direct costs of care) for the spinal cord injury population.
- There are several choices of surfaces using various technologies, as a crucial part of the strategy for prevention and treatment of pressure injuries following a spinal cord injury.
- The selection of a bed and mattress in individuals at risk of pressure injury development should be based on a multidisciplinary approach, including the patient, considering specific risk factors of pressure injuries.
- Further research is essential to improve pressure redistribution effectiveness and aid in the decision-making process. These achievements may represent important steps for the treatment and prevention of pressure injuries.

Summary points

- Pressure injuries (PI) are of a main concern for individuals with spinal cord injury (SCI). No other preventable event occurs as frequently, occurring at a rate of 2%–40% of all acute care hospitalization in United States and Canada. The recent literature estimates that hospital-acquired PI among SCI patients ranges from 29.7% to 49.2%, which represent enormous costs for healthcare systems.
- The selection of a support surface is a critical component of a comprehensive plan for PI prevention and treatment. There are two main groups of pressure-redistribution support surfaces for the prevention and treatment of PI: (1) reactive and (2) active, which are then stratified based on their mechanism of action and features.
- Overall, with the current state of evidence, it is impossible to determine the most effective support surface for either prevention or treatment. It is thus suggested to assess patient's characteristics in a holistic way before selecting a support surface based on its various properties during loading.
- Selection of support surface may be managed by a multi-disciplinary team, ideally including the patient (if possible), and must take into account many factors, such as the level of mobility, medical status previous or current pressure injuries, and other specific risk factors of pressure injuries.
- Despites the efforts devoted to the development of emerging technologies, further research is warranted in both clinical and fundamental context, to better determine and improve the efficiency of pressure redistributing technologies for prevention and treatment of pressure injuries.

FDP	flexor digitorum profundus
FLP	flexor pollicis longus
EPL	extensor pollicis longus
ECD	extensor communis digitorum
PT	pronator teres
CMC	carpometacarpal
IP	interphalangeal
EPI	extensor proprius indicis
EDM	extensor digitorum minimi
FCU	flexor carpi ulnaris
FP	flexor pollicis
MP	metacarpophalangeal

Introduction

The most common causes of spinal cord injury (SCI) are road accidents and falls from a height, with a prevalence for male patients between 16 and 30 years old (Titolo et al., 2019) and an incidence between 10 and 80 new cases per millions of people annually worldwide (Kumar, Osman, & Chowdhury, 2017).

More than 50% of all spinal cord injuries involve cervical spine leading tetraplegia as main clinical feature, with loss of effective upper-limb function.

The lack of hand function is the sequela which mostly affected the quality of life in patients with tetraplegia and always requires support in their daily-life activities and mobility from other people (Anderson, 2004; Bednar & Woodside, 2018; Waters, Sie, Gellman, & Tognella, 1996). Furthermore, it is reported as more desired than bowel, bladder and sexual function, standing and pain control (Anderson, 2004; Brown, 2011). In this scenario, tendon transposition is a reliable surgical technique able to restore active movement and strength of a damaged anatomical segment; however, the shortage of functional muscles above the segment lesion available for transfer is the main problem treating cervical SCI (Titolo et al.,

Diagnosis and Treatment of Spinal Cord Injury. https://doi.org/10.1016/B978-0-12-822498-4.00023-3

2019). Similarly, nerve transfer required the adjustment of a healthy donor nerve to a denervated anatomical district to restore function nerve-target, but this means to sacrifice a potential useful nervous structure (Limthongthang, Bachoura, Songcharoen, & Osterman, 2013).

In our review, we are going to illustrate the current available techniques of tendon and nervous transfer in order to restore hand and forearm function combining nerve and tendon transfer in patients with tetraplegia.

Classifications

The most useful and accepted classification for upper-limb lesion in tetraplegia is the:

The Classification for Surgery of the Hand in Tetraplegia (ICSHT), where, the most common patterns of injuries are classified following the number of functional muscles existing below the elbow.

A functional muscle is described as muscle graded 4 or more according to the Muscle Grading System (James, 2007) (Table 1), and the ICSHT principles are reported in the literature as the "gold standard" to choose the most appropriate reconstructive technique mainly based on tendon transfer and tenodesis procedure (Table 2).

It's important to select the most appropriate donor muscle in order to preserve function of anatomical region without creating another functional deficit after tendon transfer which can be used alone or in combination with tenodesis and arthrodesis showing interesting and reproducible results (Bednar & Woodside, 2018).

TABLE 1 International Classification for Surgery of the Hand in Tetraplegia (ICSHT).

Motor GROUP	Characteristics	Function
0	No muscle below elbow suitable for transfer	
1	BR	Flexion and supination of the elbow
2	ECRL	Extension of the wrist
3	ECRB	Extension of the wrist
4	PT	Pronation of the wrist
5	FCR	Flexion of the wrist
6	Finger extensors	Extrinsic extension of the fingers
7	Thumb extensor	Extrinsic extension of the thumb
8	Partial digital flexors	Extrinsic flexion of the fingers
9	Lacks only intrinsics	
10	Exceptions	

BR brachioradialis, ECRL extensor carpi radialis longus, ECRB extensor carpi radialis brevis, PT pronator teres, FCR flexor carpi radialis.

TABLE 2 Muscle Grading System of the British Medical Research Council, muscle function ranged from 0 (no contraction) to 5 (normal power).

GROUPS	Description
0	No contraction
1	Flicker or trace of contraction
2	Active movement with gravity eliminated
3	Active movement against gravity
4	Active movement against gravity and resistance
5	Normal power

According to function importance, a priority order to choose the correct sequence of donor muscles (Limthongthang et al., 2013; Zlotolow, 2011) is well established:

(1) wrist extension recovery,
(2) pinch recovery,
(3) grasp recovery,
(4) finger and thumb extension recovery,
(5) intrinsic muscles function recovery.

When transfer options are ended, the remaining functions are reached using tenodesis and arthrodesis (Titolo et al., 2019).

In the setting of arm dysfunction, nerve transfer is also a successful surgical procedure approaching proximal brachial plexus injury with avulsion of nerve roots or more peripheral nerve injuries. Nerve transfers are commonly used where anatomic repair of original motor nerve is not possible as well as where it's possible to rapidly restore function by rerouting expendable donor nerves (de Mendonça Cardoso, Gepp, Lima, & Gushiken, 2020). Recently, some Authors introduced nerve transfers in tetraplegia, reporting interesting outcomes (Mooney, Hewitt, & Hahn, 2020; Titolo et al., 2019). According to our previous work (Titolo et al., 2019), the current authors propose a new surgical strategy based on classical tendon transfer surgery combined with nerve transfer techniques (Table 3). The use of both surgical approaches allows avoiding a frequent concern about the use of nerve transfer in reconstructive surgery: the risk of using sources of "predictable" results for "unpredictable" results.

In this proposed technique, the choice of the most appropriate nerve donor site is crucial in order to avoid the subtraction of useful muscles; in this way, it is always possible to perform a second stage surgery according to classical tenodesis or tendon transfer surgeries.

Indications and timing

The standard patient candidate to combined nerves and tendons transfer is a patient with cervical spine injury, with incomplete or partial paralysis of the upper limb and a stabilized upper extremity motor function.

Their general condition should be considered stable, with good pain control, no spasticity and infection free. The passive range of motion could be almost complete and they should be very motivated for the long postoperative rehabilitation (Fox et al., 2019).

Patients should be correctly informed before surgery, especially about the difference in terms of recovery time: nerve transfer needs a long time before they can show their results, and often they need a second stage procedure to achieve the set objectives. Great motivation and realistic objectives are strongly requested to obtain good improvement in hand function (Gohritz et al., 2007).

Conversely, contraindications for nerve and tendon transfer surgery which could lead to poor results, are (Lee & Wolfe, 2012) spasticity contractures, chronic pain problems, psychological instability with unrealistic expectations and insufficient motivation.

However, there is no consensus about timing of nerve transfers in tetraplegia. Unfortunately, within the year from injury, all possible spontaneous recovery has already occurred; for this reason, it is recommended to perform tendon transfer after 1 year from SCI. Nevertheless, the neurological recovery usually occurs in the first 6 months from trauma (Lee & Wolfe, 2012).

It is usually accepted that terminal muscular atrophy is established after 1 year of denervation, with no possibility of function restoration (Fu & Gordon, 1995a, 1995b). According to these premises, Lamb and Chan observed that if a muscle is completely paralyzed during the initial assessment and it will remain paralyzed 1 month later, it will be rare to observe any significant improvement, even 1 year later (Lamb & Chan, 1983). On the contrary, Bertelli et al. reported functional muscle reinnervation after distal nerve transfers performed 18 months after SCI (Bertelli & Ghizoni, 2013).

Furthermore, Fox et al. described two type of lesions with different indications about the appropriate surgical time for intervention (Fox, 2016) (Fig. 1).

First, time-independent lesions: clear-cut SCI with a little zone of cell damage located at the anterior horn of the spinal cord. Peripheral nerve transfer can restore segment movement by reconnecting functional motor unit to brain. This transfer switches the motor control from an expendable donor to a muscle group distal to lesion level, bypassing the site of lesion. It can be done at any time after trauma.

Second, time-dependent lesions: injury site is more extensive; roots can be involved as a peripheral nerve lesion. To restore the voluntary control or to reinnervate muscles that would become atrophic nerve transfer should be used.

TABLE 3 Combining Nerve and Tendon Strategy in tetraplegia.

Group 0		
Primary procedure	**Positive outcome?**	**Secondary procedure**
• Teres minor to triceps nerve transfer • Brachialis to ECRL nerve transfer	NO	Posterior deltoid to triceps tendon transfer
	YES	Flexor pollicis longus tenodesis + Moberg key pinch procedure

Group 7 (EPL → M 4)		
Primary procedure	**Positive outcome?**	**Secondary procedure**
• Brachialis to AIN/FDS nerve transfer	YES	EDM to APB or EIP to APB
	NO	BR to FPL tendon transfer + Tenodesis FDP 2° to FDP 3°-4°-5° + EDM to APB or EIP to APB
• ECRL to FDP (3°-4°-5° finger) tendon transfer		
Group 8 (partial finger flexion)		
Primary procedure	**Positive outcome?**	**Secondary procedure**
• ECRB to AIN nerve transfer	YES	EPI/EDM to opposition
	NO	BR to FPL tendon transfer + Tenodesis FDP 2° to FDP 3°-4°-5° + EPI/EDM to opposition
Group 9 (intrinsic deficit)		
Primary procedure	**Positive outcomes**	**Secondary procedure**
• Intrinsic reconstruction (Zancolli lasso/ house intrinsic procedure) • Opponensplasty	YES	None
	NO	

A new proposal of surgical treatment based on ICSHT group. In case of failure of the proposed treatment, a salvage procedure (actual treatment) is always possible.

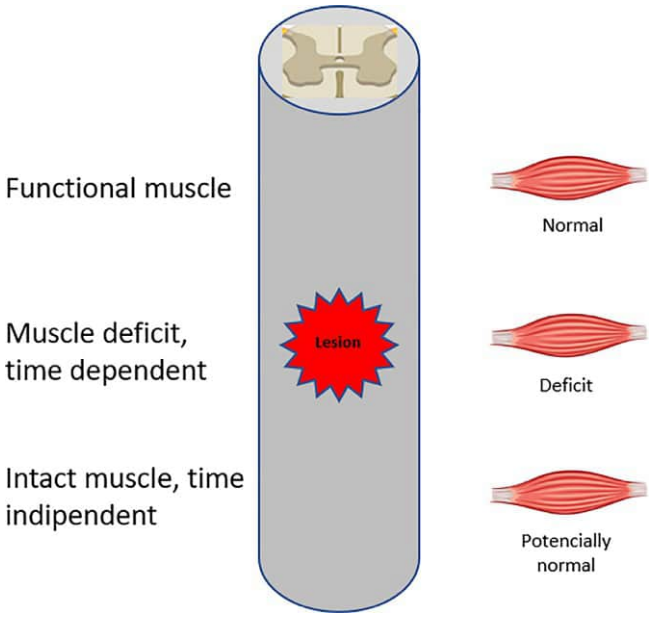

FIG. 1 Time-dependent and time-independent injury based on the level of spinal cord lesion.

Denervated muscles might benefit from early surgery before the onset of muscular atrophy, while paralyzed muscles leave more time for surgery (Cain, Gohritz, Fridén, & van Zyl, 2015; Fox et al., 2018).

Taking into account all these factors, an ideal time for surgery should be performed between 6 and 12 months from trauma, before the onset of irreversible muscle atrophy. Procedures could be anticipated only if muscles denervation is recorded by electromyography (EMG) (Bertelli, Ghizoni, & Tacca, 2011).

In the following paragraphs, we will describe primary and secondary procedures for each group of ICSHT classification (Table 3).

Group 0

Neurological level of injury: C5.

Residual motor function: no muscle of grade 4 below the elbow.

Current reconstructive strategy: In this group, tendon transfer procedures can be performed to restore elbow extension:

- Moberg's procedure based on posterior deltoid to triceps transfer.
- Zancolli's procedure based on biceps to triceps transfer (Arnet, Muzykewicz, Fridén, & Lieber, 2013; Moberg, 1990; Muzykewicz, Arnet, Lieber, & Fridén, 2013). Conventional surgery considers useless any tendons transfers to restore wrist and hand function in this group. The restoration of wrist extension is really important, since tenodesis can allow thumb-to-index key pinch, due to wrist motion. It is also important because it increases patient autonomy, and it improves some daily life activities such as eating, personal care and wheelchair propulsion.

In one larger series, groups 0 and 1 are often together and represent almost 30% of the lesions (Lee & Wolfe, 2012).

Our proposal: It is possible to treat this condition with nerve transfer:

- teres minor to triceps nerve transfer.
- brachialis to extensor carpi radialis longus nerve transfer.

The transfer of teres minor motor branch to triceps long head motor branch allows patients to restore elbow extension without any deficit to the donor site area (Bertelli et al., 2011). Infraspinatus muscle is able to compensate external rotation deficit due to the teres minor nerve transposition. Moreover, teres minor transfer is not typically used in tetraplegia since this transfer doesn't preclude Moberg's procedure as a second surgery in case of failure or to improve a partial recovery.

Bertelli also proposed the use of the posterior division of the axillary nerve to the triceps long and medial head nerve (Bertelli & Ghizoni, 2013); however, if this procedure fails, it is not possible to use posterior deltoid tendon transfer to triceps (Moberg procedure) as salvage procedure.

It is extremely important to fully evaluate shoulder function and to explore any partial deficit of deltoid or teres minor muscle function, since if a deficit is present, it is not possible to use deltoid to restore elbow extension.

Fridén suggested the selective nerve transfer of brachialis to extensor carpi radialis longus (ECRL) to restore wrist extension (Fridén & Gohritz, 2012). Brachialis muscle is primarily innervated by a single branch of the musculocutaneous nerve deriving from the spinal roots C5/6; if biceps is working, this branch can be used as a donor. However, this will not allow a secondary Zancolli's procedure to restore elbow extension.

If brachialis transfer will have positive outcome, the lesion will upgrade from type 0 to type 1 and it is possible to perform flexor pollicis longus tenodesis and Moberg procedure for passive key pinch reconstruction (Wolfe et al., n.d.).

Group 1

Neurological level of injury: C5.

Residual motor function: only brachioradialis (BR) is graded as 4 or more. Elbow flection is still possible since brachioradialis and biceps are functioning.

Current reconstructive strategy: As for group 0, Moberg or Zancolli's procedure can be used to restore elbow extension. The transfer of BR tendon to radial wrist extensors is able to provide enough strength to extend wrist against resistance.

Our proposal: It is possible to transfer:

- Teres minor to triceps nerve.
- Brachialis to anterior interosseous nerve (AIN) and flexor digitorum superficialis (FDS) nerve transfer.
- BR to extensor carpi radialis brevis (ECRB) tendon transfer.
- BR to ECRB tendon transfer is able to restore active wrist extension and passive key pinch reconstruction thanks to flexor pollicis longus (FLP) tenodesis with some tricks (Hentz, House, McDowell, & Moberg, 1992; House, Gwathmey, & Lundsgaard, 1976; Johanson, 2016).

About 10 years ago, Mackinnon described the brachialis to AIN transfer in patients with spinal cord injury (Mackinnon, Yee, & Ray, 2012). In this way, it is possible to improve intrinsic hand muscles function, which are very important to increase grip strength and ability, allowing patients to self-feeding (van Zyl et al., 2014).

If it is possible to partially restore flexor pollicis longus function, this will improve tenodesis effects grasp and provide extra strength and holding power as described by Fox et al. They used brachialis to AIN and FDS nerve transfer for this purpose (Fox et al., 2015a, 2015b, 2018).

If these procedures have good results, with restoration of pinch function, a second stage procedure can be planned to increase grip strength. ECD and EPL can improve hand opening and grasp function. In case of failure, FLP tenodesis can be performed anyway at any time.

Group 2

Neurological level of injury: C6.

Residual motor function: both BR and ECRL graded 4 or more; however, it is difficult to discriminate the differential strength between ECRL (group 2) and ECRB (group 3). It is possible to discriminate between the two groups with different tests, but none of them seems to be really effective:

- Bean's sign (Mohammed, Rothwell, Sinclair, Willems, & Bean, 1992).
- Surgical exploration (Hentz et al., 1992; Moberg, 1990).
- Pronator Teres (PT) as marker of function (Allieu, 2002).

Current reconstructive strategy: surgery aims to obtain an effective key-grip thumb function, and it is usually obtained with House one-stage active key-pinch reconstruction. This technique involves:

- BR to FLP tendon transfer.
- FLP split and arthrodesis of IP joint of the thumb (Henz procedure).
- Carpometacarpal (CMC) fusion.
- Tenodesis of EPL to balance the flection tendency (House, Comadoll, & Dahl, 1992).

Other authors preferred to perform ECRL tendon transfer, only if ECRB has normal strength, while they suggest to avoid this procedure if strength is graded 4 or less (Hentz et al., 1992).

Our proposal: The purpose of nerve transfer in this group is to obtain a functional and effective pinch to allow and active fingers flexion and extension, along with elbow extension:

- Teres minor to triceps nerve transfer.
- Supinator to posterior interosseous nerve (PIN) transfer.
- Brachialis to AIN transfer.
- FDS nerve transfer.

Motor branches for supinator come out from PIN, which is the distal motor division of radial nerve for the forearm. When the lesion is at C6 level, some muscles innervated from radial nerve are still functioning. Supinator is innervated from neuronal cell above the site of lesion and it could be used to partially restore fingers and thumb extension.

Supinator is always functional when there are strong wrist extensors, and a sacrifice of supinator will not affects supination function since it will be allowed by biceps (Bertelli, Tacca, Ghizoni, Kechele, & Santos, 2010).

The objective of nerve transfers is to allow reinnervation of ECD, EPL, abductor pollicis longus and extensor pollicis brevis, in order to preserve trapeziometacarpal joint mobility and avoid tenodesis of abductor pollicis longus. Moreover, the reinnervation of extensor carpi ulnaris allows a secondary transfer to flexor carpi ulnaris to stabilize the wrist during finger extension (Bertelli et al., 2010).

In long time tetraplegia with no response of PIN from electric stimulation, Bertelli also proposed a free gracilis muscle transfer for thumb and finger extension with innervation supplied by supinator (Bertelli & Ghizoni, 2016).

- In case of failure of teres minor motor branch to triceps long head motor branch, it is possible to perform a secondary salvage procedure with posterior deltoid tendon to triceps transfer (Moberg procedure).
- In case of failure of supinator to PIN transfer, it is possible to undertake a salvage procedure with ECD and EPL tenodesis
- If nerve branch of brachialis to AIN transfer reached good functions, the procedure could be completed by BR tendon transfer with a tendinous graft in order to strength thumb opposition (House et al., 1976).

In case of failure, it is always possible to perform the House one-stage active key pinch reconstruction to restore key-pinch.

Group 3

Neurological level of injury: C6.

Residual motor function: both ECRL and ECRB are graded 4 or more.

Current reconstructive strategy: it is based on Zancolli's procedure (Zancolli, 1979), which consists of two steps:

(1) restoration of extension function
(2) restoration of flexion function

For the first stage it is suggested to perform an extensor tenodesis (ECD and EPL), a "lasso procedure" and a thumb IP joint fusion. The Zancolli's "lasso procedure" aimed to prevent MP joint hyperextension and clawing of the fingers during extension; FDS is used to perform MP joint flexion (Wolfe et al., n.d.).

In the second stage, ECRL to FDP and BR to FLP tendon transfer could be performed.

Some author prefer to treat this group of lesions as group 2 in order to prevent the loss of wrist strength using House's one stage active key pinch reconstruction along with a "lasso procedure" if the index finger doesn't flex enough to allow the key pinch (Mohindra, Gogna, Sangwan, Gaba, & Kundu, 2017).

Our proposal: combination of nerve and tendon transfer:

- teres minor to triceps nerve transfer,
- supinator to PIN nerve transfer,
- brachialis to AIN and FDS nerve transfer,
- ECRL tendon to FDP tendon transfer for 3-4-5 finger.

In case of failure of teres minor nerve transfer, the salvage procedure consists in Moberg procedure, while if supinator to PIN nerve transfer fails, to restore thumb and finger extension it is possible to perform ECD and EPL tenodesis.

It also possible to transfer ECRB nerve to AIN, as described by Bertelli, and if it fails, a salvage procedure with brachioradialis and brachialis tendon transfer for finger flexion (Bertelli, 2015).

Recently, experiments on ECRB nerve to AIN transfer, showed recovery of fingers flexion. This could be related to intermuscular nerve connections between AIN and ulnar nerve (Bertelli & Ghizoni, 2017).

We prefer to spare ERCB for secondary tendon transfer, and we prefer to perform brachialis nerve to AIN transfer, since ERCB tendon transfer is a very reliable and suitable technique to obtain finger flexion.

While waiting for extension function recovery (due to supinator to PIN transfer), finger flection imbalance can be temporarily managed with a radial nerve palsy splint, or, in case of nerve transfer failure, with extensor tenodesis as secondary procedure.

According to our experience, if the brachialis nerve to AIN transfer has a good outcome, an independent index finger pinch function could be obtained without the need to primarily transfer ECRL to FDP. Thumb opposition can be improved with BR tendon transfer (House et al., 1976).

If brachialis nerve to AIN transfer fails, it is possible to perform tenodesis of index finger FDP to other fingers (3rd–4th–5th). Moreover, it is possible to perform additional procedures, depending on secondary recovery:

- FLP splint.
- arthrodesis of IP joint.
- CMC fusion.

Group 4

Neurological level of injury: C7.

Residual motor function: PT strength with grade 4 or more.

PT could be considered for tendon transfer, but it is necessary to pay attention to its important role in wheelchair propulsion.

Current reconstructive strategy: House reconstructive strategy of a two-stage reconstruction of grasp and release function.

Extensor phase is performed first and consists in three surgical steps:

– CMC fusion and ELP tenodesis.
– ECD tenodesis to the distal radius or BR to ECD transfer.
– Intrinsic tenodesis using a free tendon graft routed to the lumbrical canals (House et al., 1976).

Flexion phase is performed later and it is divided into 2 different steps:

(1) BR or PT transfer to FLP
(2) ECRL to FDP

It is also possible to improve opposition with BR or PT with FDS graft.

If PT instead of BR is used for FLP tendon transfer, BR could be used to restore adduction—opponens function, using paralyzed FDS, which can be considered an "in situ tendon graft"(Wolfe et al., n.d.).

Our proposal: same as group 3, but in this case, it is not necessary to transfer teres minor to triceps since in this group triceps strength is normal.

In alternative, it is possible to perform PT to FDS nerve transfer (Titolo et al., 2019).

Two branches of the median nerve innervate the PT and the transfer of 1 branch to ECRL in high radial nerve palsy is able to restore almost complete wrist extension (grade 4), preserving at least a grade 4 pronation strength (García-López, Navarro, Martinez, & Rojas, 2014).

It is possible to perform:

– supinator nerve to PIN transfer.
– brachialis nerve to AIN and FDS nerve transfer.
– tendon transfer of ECRL to FDP of the 3rd–4th–5th finger.

Since the lesion is more caudal, BR, ECRL and PT are available for tendon transfer. Usually, ECRB should be preserve in order to stabilize wrist joint (Lee & Wolfe, 2012; Wolfe et al., n.d.).

In radial nerve palsy, pronation of the forearm can be achieved by pronator quadratus, FCR, FDP, and FDS contraction. For that reason, it is difficult to retrieve which is the real pronation deficit in group 4.

In normal hand, complete pronosupination movement can be achieved with BR, extensor carpi ulnaris and EDM (Bertelli & Ghizoni, 2017; Bertelli, Ghizoni, & Tacca, 2016); however, in this group only brachioradialis would still

produce a partial pronation in case of deficit of PT. Since PT is fundamental for wheelchair propulsion, we suggest to avoid PT or FDS nerve transfer. It is possible to perform a secondary House intrinsic procedure.

Group 5

Neurological level of injury: C7.

Residual motor function: FRC graded 4 or more.

It is possible to transfer supinator to PIN nerve, brachialis nerve to AIN and FDS, while it is possible to transfer the tendon of ECRL to FDP of the 3rd–4th–5th finger.

Current reconstructive strategy: same of group 4.

Our proposal: same of group 4. FRC can be transferred to PIN or AIN (García-López et al., 2014), but in our practice, we prefer to spare FRC in place to preserve the maximal wrist control possible (House et al., 1992).

Group 6

Neurological level of injury: C7.

Residual motor function: ECD graded 4 or more. Extensor phase is not necessary in this type of patients and surgery is focused on flexor phase only.

Patients have a "flat hand" because digital extension is not opposed by antagonist muscles, with lack of active grasp. Since the lesion is at C7 level and not above, patients have a perfect control on shoulder, elbow and wrist to control the position of the hand in space, so they will benefit from grasp and reconstructive surgery.

Current reconstructive strategy: same of flexion phase of previous two groups.

Our proposal:

- Brachialis to AIN and FDS nerve transfer.
- EPL tenodesis and ECRL to FDP of the 3rd–4th–5th finger tendon transfer.

The EPL is very weak or totally absent, while finger active extension is strong. For this reason, it is useful to perform a tenodesis of EPL or a transfer to EDC to improve thumb extension.

Some authors proposed to transfer ECRB (extensor carpi radialis brevis) terminal motor branch to FLP (flexor pollicis longus) nerve to reconstruct thumb flexion and brachialis tendon transfer with graft to restore fingers flexion (Bertelli et al., 2012; Bourrel, 1974; Mangus, 1973; Zancolli, 1979).

We suggest to spare ECRL nerve and to use a tendon transfer to obtain fingers flexion. It is also possible to perform a House intrinsic procedure to complete the surgical procedure.

Group 7

Neurological level of injury: C8.

Residual motor function: EPL graded as 4 or more. Fingers and thumb extensors are complete functioning and only flexor phase reconstruction is needed.

Current reconstructive strategy:

- ECRL to FDP tendon transfer.
- BR or PT to FLP tendon transfer to restore active pinch as for the previous group.

A possible alternative is based on Brachialis to AIN and FDS nerve transfer and ECRL to FDP of the 3rd–4th–5th finger tendon transfer.

Thumb control can be improved with CMC fusion and opponens plasty depending on thumb control and patient's preference. A Lasso procedure can be also performed to improve digital grasp (Gupta, Consul, & Swamy, 2015).

Our proposal: same steps of group 6 but avoiding EPL tenodesis. Moreover, we perform also Extensor Indicis Proprius (EPI) or EDM opponens plasty. A further intrinsic reconstruction procedures as suggested by Zancolli (Zancolli, 1979) and Bourrel (Bourrel, 1974) can be added to achieve the desired results.

Group 8

Neurological level of injury: C8 level.

Residual motor function: intact FCU and partial FDP. The flexors of 4th and 5th fingers are usually stronger than those of first three fingers.

Current reconstructive strategy: aim of surgical intervention is to restore fingers flexion using Zancolli's two stage reconstruction: extrinsic transfers and intrinsic reconstruction.

- Extrinsic transfer:
  - side to side suture of the four profundus tendons and half of the index FDP is woven together with other tendons to ensure right tension;
  - a secondary additional part is the BR or PT to FLP transfer.
- Intrinsic reconstruction:
  - Zancolli lasso technique,
  - opponensplasty with EPI or EDM plus CMC fusion or intrinsic tenodesis as described by House et al., 1976.

To achieve an independent flexion of the index it is possible to perform ECRB to FP of the 2nd digit tendon transfer. Intrinsic function reconstruction may always be performed as a second step procedure.

Our proposal: ECRB nerve branch pro AIN nerve transfer (Allieu, 2002; House et al., 1992).

If the procedure fails, House's one-stage active pinch reconstruction can be performed anyway along with Henz procedures. The flexion tendency will be balanced by CMC fusion and EPL tenodesis, while complete hand function will be restored through tenodesis of FDP of second finger to 3rd–4th–5th finger FDP.

Group 9

Neurological level of injury: C8-T1.

Residual motor function: FDS and other extrinsic muscle for fingers and thumb flexion, with lack of intrinsic muscle function.

Current reconstructive strategy and our proposal: surgical intervention aim to restore intrinsic nerve function. Opponensplasty and intrinsic reconstructions can be performed according to the intrinsic imbalance present (Titolo et al., 2019).

A resulting claw deformity of fingers with hyperextension of MP joints can be treated with Zancolli passive or active lasso procedure (Gupta et al., 2015; Zancolli, 1979), while House intrinsic tenodesis can be used to treat PIP flexion deformity (House et al., 1992).

Conclusions

Thanks to new advances in the field of nerve transfer, it is possible to fuse the old concepts of tenodesis and tendon transfer for tetraplegic patients with the new approaches based on nerve surgery to improve upper-limb function.

The fusion between old and new approaches could widen therapeutic choices for this kind of patients, sparing some tendon transfers as salvage procedure which could always be useful in case of combined approach failure.

Applications to other areas of neuroscience

Nerve and tendon transfers are a new surgical approach based on the combination of both techniques. Each technique has some indication and contraindication, which can preclude the chance to get the best result. The principle of tendon transfer is based on the transposition of an expendable tendon to achieve a primary function; however, this is not always possible since higher is the medullary lesion, less functional muscle-nerve unit you have. On the other hand, nerve transfer offers the chance to reinnervate muscle distal to the site of lesion; however, there is no guarantee of success.

Despite recovery of hand function being the most important goal for patients with tetraplegia, combined nerve and tendon transfer can also offer some choice of treatment in patients with lower-limb nerve injury (Park & Casale, 2020).

The recovery of leg motor function due to a combination of nerve and tendon transfer could represent a new perspective in the recovery of walking and standing function (Crowe, Mosca, Osorio, Lewis, & Tse, 2020).

Mini-dictionary of terms

Spinal Cord Injury. Lesion of the central nervous system with loss of function below the level of injury.

Cervical Spine. Upper region of the spine deputy to control of motor function of the upper limb.

Complete Spinal Cord Injury. Lesion involving whole spinal cord with complete loss of function.
Incomplete Spine Cord Injury. Lesion involving a part of spinal cord with preservation of some function.
Tetraplegia. Loss of function of whole body below the level of injury with loss of function in both upper and lower limbs.
Paraplegia. Loss of function of whole body below the level of injury with conservation of function in upper limbs.
Tendon Transfer. Surgical procedure where the tendon insertion is moved, while the origin remains in the same location. It involves redistribution of muscle power, and generally, tendons are transferred from lesser to more important functions.
Nerve transfer. Surgical procedure used in nerve injury with complete loss of muscle function. It involves sacrificing nerve with less important function or redundant branches of a nerve and using it to innervate a target muscle.
Tenodesis. Surgical procedure of fixation of the distal end of a tendon to a bone.
Arthrodesis. Surgical procedure of fusion of a joint with loss of mobility but increase of stability.
Salvage procedure. Procedure to achieve an acceptable result in case of failure of other surgical procedure.

Key facts of nerve and tendon transfers in tetraplegia: A new narrative

Key facts of nerve and tendon transfer

Restore motor function of upper limb in patients suffering from tetraplegia is very important to gain some level of autonomy.
In time-independent lesion, surgery can be performed at any time.
In time-dependent lesion, surgery should be performed as earlier as possible.
Generally, surgery should be performed between 6 and 12 months from injury.
Tendon transfer is the current surgical strategy used to treat tetraplegic upper limb, with fast recovery of function, but with some limitation.
Nerve transfer is a new surgical approach to restore motor function; however, the results are less fast and certain.
Combination of nerve and tendon transfer can overcome the limits of each technique, assuring better recovery of function.
In case of failure, a conventional surgical approach is always possible as salvage procedure.

Summary points

- Usually, SCI occurs after major trauma due to fall from height or motor vehicle accident.
- The restoration of upper-limb function offers patients with tetraplegia some kind of daily living autonomy.
- More distal is the level of injury, more muscles are spared and can be used for tendon and nerve transfer, and more functions are achieved.
- Usually, surgery should be performed between 6 and 12 months from injury for both time-dependent and -independent injury.
- Combination of nerve and tendon transfer is able to overcome the limits of each technique.
- Arthrodesis procedure should be considered to complete nerve and tendon transfer procedures to achieve the best results.
- In case of failure, the current approach of tendon transfer and tenodesis could always be performed as a salvage procedure.

Chapter 24

GEMINI-supported spinal cord transplantation for the treatment of chronic spinal paralysis: Overview and initial clinical translation

X.P. Ren[a,b], P. Henderson[c], C.Y. Kim[a,b,d], and S. Canavero[a,b]

[a]*Global Initiative to Cure Paralysis (GICUP), Department of Orthopedics, Ruikang Hospital, Nanning, China;* [b]*Heaven/Gemini Global initiative, Turin, Italy;* [c]*Microsurgical Research Society, Icahn School of Medicine at Mount Sinai, New York, NY, United States;* [d]*Konkuk University School of Medicine, Seoul, South Korea*

Introduction

There is at present no biological cure for chronic paralysis following spinal cord injury (SCI). A medley of experimental approaches have been tried over the years, and, despite some improvement in some patients, no full recovery has been observed (Ren, Kim, & Canavero, 2019). As underscored by Illis,

> *"it would be difficult to find any other branch of science with over a century of such sterile endeavour. In effect, there has been repetition of the same idea, albeit with different techniques, that is, looking at the lesion site. Are we sentenced to repeating the same experiments in the hope of expecting a different result?"*
>
> (Illis, 2012).

Work conducted mainly by US neurosurgeon L. Walter Freeman more than half a century ago suggests that a permanent, biological cure is possible, at least in several cases of chronic SCI, by removing *en bloc* the "*lesion site*," i.e., the most damaged portion of the spinal cord, and connecting the two free undamaged ends, after spinal (vertebral) shortening (Freeman, 1963; see also Canavero & Ren, 2016a). Transplantation of a healthy segment of cord is an alternative (see below).

In both scenarios, a technology that allows the functional reconnection of the severed ends is necessary. In 2013, the GEMINI spinal cord fusion (SCF) protocol was proposed with this goal in mind (Canavero, 2013, 2015).

Here, we will briefly review the GEMINI SCF protocol and lay out the various alternatives for its ongoing deployment in the clinical setting.

The GEMINI spinal cord fusion protocol: Overview

The GEMINI spinal cord fusion protocol is predicated on four pillars (Canavero, 2015; Canavero & Ren, 2020; Canavero, Ren, Kim, & Rosati, 2016):

1. Sharp severance of the spinal cord with an ultra-thin blade, with its attendant minimal tissue damage, as compared to clinical SCI (<10 N vs 26,000 N)
2. Exploitation of the gray matter internuncial sensori-motor "highway" (so-called cortico-trunco-reticulo-propiospinal pathway; C-TRPS) re-bridged by sprouting connections between the two re-apposed cord stumps. This "highway" runs in parallel to corticospinal descending fibers and is co-responsible for sensori-motor transmission through the cord (see also Kostyuk & Vasilenko, 1979; Shik, 1983).
3. Application of "fusogens/sealants": these "seal" the thin layer of injured cells in the gray matter, both neuronal, glial and vascular; simultaneously they fuse a certain number of axons in the white matter. The pro-regenerative early scar is not inhibited, but necrosis/cavitation is.

Diagnosis and Treatment of Spinal Cord Injury. https://doi.org/10.1016/B978-0-12-822498-4.00024-5

4. Acceleration of axonal outgrowth by electrical spinal cord stimulation straddling the fusion point and concomitant motor cortex stimulation.

We will briefly review the technology involved. An in-depth discussion can be found elsewhere (Canavero et al., 2016; Canavero & Ren, 2020).

GEMINI: Fusogens

Cell fusion is the process by which the membranes and intracellular contents of any two cells are permanently fused. There are multiple situations where this occurs naturally—fertilization is one very fundamental example, but there is also increasing evidence that cell fusion can be induced for clinical benefit. The most striking clinical application of this is the potential for reconstitution of axon integrity and electrical conductivity through the fusion of axon membranes; this can be performed in order to reconnect the two cut ends of a severed axon, or to create membranous continuity between the ends of two axons that have been newly placed in apposition (such as in a allogeneic transplant). While close spatial proximity is required, and usually achieved through some sort of physical (often micro-surgical) manipulation, the scale at which this occurs is small and relies on a chemical manipulation to complete the fusion at the level of the cellular membrane. The substances that are capable of performing this function are heterogeneous in composition and function, and often referred to as "fusogens" (Ryan & Henderson, 2020).

Axon membrane fusion is valuable in any attempt to manage nerve injury because it allows for the possibility of immediate reconstitution of electrical conductivity and therefore nerve function. An outcome on such a timeline is impossible given the current standard methods for managing nerve injury (approximation via epineurial repair), which accept distal Wallerian degeneration and the need to wait for axon regeneration from the point of injury to the end organ (which is traditionally thought to progress at the rate of approximately 1 mm per day). Therefore, fusogens represent a quantum leap in the way that nerves are managed, as they allow for the possibility of true axon *repair*, as opposed to the traditional methods, which at best harness axon *regeneration* (and accordingly the outcomes after this treatment approach are partial at best, and measured on the order of months to years).

There are two general mechanisms by which fusogens are thought to function: cell aggregation and membrane modification (Ryan & Henderson, 2020). Substances that function only via cell aggregation lead to increasingly closer apposition of the two axon ends (often by extraction of intervening water molecules). This group includes chitosan, dextran sulfate, small organic molecules, and lipids. Substances that function only via membrane modification alter membrane charges to create a more favorable electrochemical environment for apposition and ultimately fusion to occur. This group includes cations such as Ca^{2+} and Mg^{2+}, sodium nitrate, and H-alpha-7. Polyethylene glycol (PEG) is a substance that is thought to function by a combination of both mechanisms, and for that reason is it is the fusogen that, to date, has been used most widely and most successfully in both research and clinical settings.

PEG is a hydrophilic polymer that is inexpensive and commonly encountered, as it has proven to play a role in many different medical, biological, and industrial scenarios. Its potential utility as a means of promoting cellular fusion, however, was first recognized in the 1970s after it was shown to be able to induce immortalized hybridoma cells and fused mammalian erythrocytes (Ren et al., 2019). The ability to induce axon membrane fusion (either in repair of cut ends of the same axon, or the fusion to ends of a different axons) was first realized and progressively tested beginning in the 1980s, starting with invertebrate models (Bittner, Sengelaub, Trevino, et al., 2016), and gradually progressing into rodents and then large mammals (fully reviewed in Canavero & Ren, 2020). It has successfully restored complete digital nerve function after traumatic injury in small human studies (Bamba, Waitayawinyu, Nookala, et al., 2016; see also De Medinaceli & Merle, 1991) and has been effective at restoring neurologic function at the level of the spinal cord in multiple animal models (Ren et al., 2019; fully reviewed in Canavero & Ren, 2020).

In addition to the cell fusion mechanisms of cell aggregation and membrane modification, PEG has been shown to have other effects that are beneficial for maximizing nerve function. First, it is neuroprotective due to its ability to inhibit the formation of the mitochondrial permeability transition pore; second, it may reduce the neuronal membrane tension and thereby improve membrane fluidity; third, it causes the release of neurotrophin-3, which attracts neural stem cells and promotes their differentiation into axons. However, PEG does not lead to the fusion or repair of connective tissue and therefore does not provide any structural strength and in very rare cases may be associated with allergic reactions (see references in Ren et al., 2019).

GEMINI: Electrical stimulation

The GEMINI SCF protocol includes the positioning of an extradural stimulating 16-contact paddle straddling the point(s) of fusion followed by continuous stimulation (15–60 Hz, 5–9 V) during the entire rehabilitation period (Canavero, 2015;

Canavero et al., 2016; Canavero & Ren, 2020). Spinal cord stimulation (SCS) is paired to non-invasive transcranial magnetic stimulation (TMS) of the motor cortex (M1) (Canavero & Ren, 2016a, 2016b).

Electrical stimulation (ES) serves two primary purposes:

1. Promotion/Acceleration of axonal outgrowth and plasticity across the fusion interface. Shirres first emphasized the ability of electricity to stimulate spinal cord regeneration (see full details in Ren et al., 2019). ES has been shown to accelerate axonal outgrowth (neural sprouting) at sites of injury, including the cord, in animal studies (e.g., Thornton, Mehta, Morad, et al., 2018; see also Jack, Hurd, Martin, & Fouad, 2020, Ju, Park, Kim, Kim, et al., 2020). Of note, ES is co-additive to PEG in SCI (Wang et al., 2016).
2. Activation/Facilitation of propriospinal neurons caudal to the fusion interface.

Following complete spinal transection in man, the neuronal networks responsible for locomotion (i.e., central pattern generators, CPG) residing in the spinal cord are intact, but fail to produce limb movements: the excitability of the spinal cord is too depressed to enable the coordinated recruitment of motor neuron pools. Consequently, enabling robust levels of activity during rehabilitation is critical to steer activity-dependent plasticity in the trained circuitry. This is achieved by ES. ES replaces missing sources of excitation to reactivate spinal circuits, and thus enable motor control. In particular, following chemical fusion, sprouting across the fusional interface restarts the flow of electrical transmission between the fused cords. ES amplifies voluntary commands from the brain and thus supports their propagation to the CPGs at cervical and lumbar levels (Canavero & Ren, 2016a, 2016b; Canavero & Ren, 2020; Minassian & Hofstoetter, 2016). In turn, these integrate supraspinal and sensory information into the execution of purposeful movements.

Over the past 20 years, on the heels of Dimitrijevic's pioneering work in the last decades of the XX century (Dimitrijevic, 1983), multiple independent laboratories have shown that the delivery of continuous electrical stimulation (tonic) over the lumbar spinal cord immediately reestablishes intentional control over the activity of previously paralyzed leg muscles, even more than a decade after the occurrence of the SCI. Continuous ES also restores full weight-bearing standing and facilitates stepping (see reviews in James, McMahon, Field-Fote, & Bradbury, 2018; Calvert, Grahn, Zhao, & Lee, 2019; Cho, Squair, Bloch, & Courtine, 2019; Jack et al., 2020; see also chapters in this volume). ES of the spinal cord (SCS) is known to elicit activity locally and rostrally up to the cortex (as shown in chronic pain: see Canavero & Bonicalzi, 2018, pp. 465–474).

Spatiotemporal SCS protocols have been touted as an improvement over continuous stimulation (reviewed in Cho et al., 2019). However, no trials exist that compare continuous with spatiotemporal stimulation in homogeneous patients. Serotonergic agonists may further potentiate the effects of ES (Calvert et al., 2019; Cho et al., 2019).

ES can be employed in conjunction with specialized multidirectional robotic body weight support systems to steer activity-dependent plasticity in response to training (Cho et al., 2019).

Although clinical experience is limited to ES of the lumbar CPG, similar results are expected for the cervical cord (Canavero & Ren, 2016a, 2016b; Sunshine et al., 2013).

Importantly, since recovery of supraspinal control over limb movements is *directly correlated with the amount of spared tissues*, ES in the present context can only be deployed *after* chemical fusion.

As mentioned, M1 is concomitantly stimulated to promote corticospinal tract axonal outgrowth and plasticity; timing of paired stimuli is leveraged to produce plasticity during the rehabilitative phase (Canavero & Ren, 2016a, 2016b; Jack et al., 2020; Song, Amer, Ryan, & Martin, 2015; Zareen, Shinozaki, Ryan, et al., 2017). Stimulation of M1 can be carried out both invasively and noninvasively (Canavero, 2009, 2014). In the present context, noninvasive cortical stimulation (NICS) by means of TMS is the preferred modality. M1 ES promotes sprouting of corticofugal fibers and modulates post-injury neuroplasticity (Canavero, 2009; Canavero & Ren, 2016a, 2016b). M1 orchestrates recovery after SCI, developing new routes through the C-TRPS (Canavero & Ren, 2020; see also Cho et al., 2019).

Clinical translation

Based on experimental evidence (reviewed in Ren et al., 2019), PEG turns out to be the fusogen of choice: it is most effective when applied locally and acutely after cord transection and stump apposition. Cord necrosis and cavitation are greatly reduced or curbed. Studies show that the molecular weight of PEG greatly affects the final outcome, with PEG 600 and PEG1500 as the ones evincing the best results in animal models of cord transection (see in Canavero & Ren, 2020).

Gemini hydrogelation

In the simplest approach, the damaged cord segment (or at least half of it) is removed, up to its border with rostral and caudal healthy tissue and the gap is filled with a PEG hydrogel. PEG can be cross-linked to form porous hydrogels, which can serve

as biocompatible matrices that can closely mimic the Extra-Cellular Matrix. PEG hydrogels possess both high water content/porosity and solidity. Injectable PEG, by in situ gelling, can conform geometrically to the defect (see Ren et al., 2019). Regenerating propriospinal fibers course through this hydrogel "superhighway," as demonstrated in rodent studies after many months (Estrada, Brazda, Schmitz, et al., 2014). Certainly, the use of PEG alone cannot completely mimic the three-dimensional porous structure of the spinal cord and would allow the upper and lower fiber bundles to grow in mismatched or even misplaced channels or pores, which is not the case with the next two approaches (see next section). Moreover, this approach would need many months for recovery. However, microspheres loaded with neurotrophins (e.g., BDNF and GDNF) could be embedded for slow release to accelerate this regrowth (see Ren et al., 2019).

Resection-apposition (Freeman-GEMINI approach)

As mentioned, Walter Freeman suggested the severance-reapposition approach to chronic SCI: he surgically removed the damaged segment of the cord in dogs creating a gap, performed a complete *en bloc* vertebrectomy thus shortening the spine, brought the two fresh cord stumps in contact with fresh plasma and sutured the dura tightly: walking animals resulted after several months (Freeman, 1963; see also Heimburger, 2005, 2006). Notably, he observed direct electrophysiological conductance across the apposed stumps and provided histological evidence of axonal regeneration across the sectional interface (see also Beneš, Druga, Rokyta, & Stastný, 1991 and De Medinaceli & Wyatt, 1993; review in Ren et al., 2019). There is experimental evidence that the transected spinal cord in rabbits too can regenerate with concomitant return of motor, sensory and sphincter function when adequate apposition is obtained (Murray, Ugray, & Graves, 1965). Others carried out Freeman's surgery in dogs either immediately (Derlon, Roy-Camille, Saillant, Poirier, & Pichon, 1978) or 7 days after full section of the cord (Lumb & Nornes, 1983). However, Street (1967) carried out Freeman's procedure in paraplegic patients without success.

Spine-shortening vertebral osteotomy (a.k.a. vertebral column resection) is a surgical technique for correcting severe spinal deformities, treating congenital spinal anomalies, e.g., cord tethering, traumatic spine dislocations, and spine tumors at both cervical and thoraco-lumbar levels (Aoun, Elguindy, Barrie, et al., 2018; Hsieh, Stapleton, Moldavskiy, et al., 2010; Mody, Bravo Iñiguez, Armstrong, et al., 2016; Qiu, Yang, Ma, et al., 2015; Steinberg, Wali, Martin, et al., 2017). In the Freeman-GEMINI variant (Canavero & Ren, 2016a, 2016b; Ren et al., 2019), section of the damaged segment of the cord is performed at the moment of removing the vertebral body; the two ends are further trimmed so that no undue pressure is exerted on either stump by pressure vectors (too much as opposed to modest-pressure would lead to squeezing and local ischemia, jeopardizing the result). PEG is applied at this moment. The vertebra is removed and stabilization carried out simultaneously. The two spinal cord ends can be kept in apposition by some kind of micro-connector system: one incorporating a micro-channel system, through which PEG circulates, has been proposed (Brazda, Voss, Estrada, et al., 2013). Systems like this allow a tension-free, precise apposition of sharply transected nerve spinal cord stumps, as required by GEMINI. Spinal cord stimulators are epidurally positioned.

Spinal cord transplantation (Shirres-GEMINI approach)

In 1905, Shirres reported his attempt to graft a segment of healthy canine cord in a human paraplegic patient: clear signs of neuroregeneration were observed on autoptic material, with initial sensory recuperation at 3 months; autopsy showed signs of neuroregeneration (see Ren et al., 2019). Forty years later, Woolsey, Minckler, Rezende, and Klemme (1944) operated on a 16-year-old male with complete loss of motor and sensory function after he was shot in his right shoulder with the bullet reaching the superior border of T4. Following laminectomy, the injured spinal cord was completely transected and replaced with a cadaveric spinal cord that had been fixed in 10% formalin for 12 days, and cleaned and sterilized with running and distilled water and 70% alcohol. No improvement in the patient's condition was noted, and the patient died almost 4 months after the surgery. Autopsy showed exceptional preservation of the transplanted graft, although with restricted regeneration and limited tissue reaction. The preservation was attributed to the preoperative use of formalin, and no explanations or related conclusion on the microscopic findings could be made.

Today, human cord grafts/transplants are once again a consideration given the availability of an effective spinal fusion protocol, i.e., GEMINI, which would be key to interfacing the donor segment with the recipient's cord stumps (Canavero, Ren, & Kim, 2021). In this variant, PEG would neuroprotect the graft/transplant until vascularization from the healthy ends of the patient. PEG hydrogels support the formation of vascularized tissue in vivo and PEG has been shown to promote angiogenesis in an SCI model (see Ren et al., 2019). The donor segment is harvested from a brain-dead organ donor at the same level of injury. All the roots would be reanastomosed (a process akin to reimplantation of avulsed nerve roots:

Carlstedt, James, & Risling, 2017, see (Canavero et al., 2021)). However, until tolerogenic protocols are developed for this contingency, immunosuppressants would be likely needed and this adds toxicity.

Depending on the length of the segment, surgical restoration of the vascular supply on one side may be required, but remains challenging with current techniques (Canavero et al., 2021).

Alternatively, a vascularized segment of the anatomically undamaged healthy cord caudal or rostral to the injury epicenter represents a suitable, interim alternative to fill the gap, as are bundles of peripheral nerves, as suggested by past animal experiments (Derlon, Roy-Camille, Lechevalier, Bisserie, & Coston, 1983; Sugar & Gerald, 1940) (modified Shirres-GEMINI variant).

Three points should be emphasized:

1. the hemicord used as a bridge in chronic SCI has undergone years of plastic readjustments (as the entire CNS: Isa, 2017), some maladaptive (e.g., in the case of cord central pain: Canavero & Bonicalzi, 2018). This might interfere with the process of recovery in some cases. However, it is well known that so-called entrenched plasticity is in fact reversible (discussed in Canavero & Bonicalzi, 2011).
2. Roots from the hemigraft have to be cut, which causes sensorimotor disruption in their respective territories of innervation. Studies of dorsal rhizotomies in human chronic pain patients verify that nearby roots take over and compensate for the resulting deficits (discussed in Canavero & Bonicalzi, 2007). Motor deficits would affect chest and abdominal wall muscles in a limited area.
3. The entire anatomical layout is disrupted. However, as mentioned (see above), it is the gray matter that supports locomotor recovery, even if white matter bundles are misaligned and not in continuity. This bridging segment is basically a gray matter bridge through which sensorimotor transmission is restored.

In all cases, PEG and electrical stimulation are deployed. PEG alone leads to remarkable recovery, but this is expected to be boosted by spinal cord and motor cortex stimulation (see above; reviewed in Canavero et al., 2016; Canavero & Ren, 2020).

Current human trial

CANINE TRIAL: A preliminary canine study of the modified Shirres-GEMINI approach has been conducted on four female Beagles in China. In this proof-of-principle canine trial, paralysis following removal of an entire 3 cm long segment of the cord was at least partially reversed by a pedicled autograft of the animal's hemicord treated with PEG at the contact interfaces (Fig. 1). At 6 months the final average motor score (canine 0–19 Basso-Bresnahan-Beatty scale, cBBB) was roughly in line with our previous canine PEG studies of a complete spinal cord transection (medians: respectively 11.5 vs 11: Table 1) (reviewed in Ren et al., 2019). The main differences were a slower onset of symptom reversal (17 days vs 3 days) and lower final top scores (12 vs 18). This is likely due to the need for re-growing fibers to cross two, instead of one, sectional levels and more prolonged neuroplastic rearrangement than a simple section. Sphincter control was not regained at 6 months. DTI and histology data verified a vigorous regrowth of fibers across the lesional interfaces (Figs. 2 and 3).

HUMAN TRIAL: On the heels of the above study, a clinical trial was approved by the Medical Ethics Committee of Ruikang Hospital Affiliated to Guangxi University of Traditional Chinese Medicine. Inclusion criteria are: (1) Age < 50 - years old; (2) Thoracic or thoraco-lumbar traumatic-only SCI; (3) Interval from injury >12 months; (4) Absence of neuropsychiatric conditions; (5) Normal cardiopulmonary function. Surgical removal of any fixation devices was carried out in consenting patients. All patients were then submitted to Magnetic Resonance Imaging (MRI), Diffusion Tensor Imaging (DTI), Computerized Tomography (CT), Somatosensory Evoked Potential (SEP), and Motor Evoked Potential (MEP). Initial enrollment included 13 paraplegic patients (9 men, 3 women) classified as American Spinal Injury Association (ASIA) grade A. The goal of this study was to test the two arms (chemical and electrical) of the GEMINI SCF protocol singly (chemical only) or combined and compare long-term results and speed of recovery of both cord autografts and peripheral nerve bridges. Ten male (age range: 14–46 years) and three female (age range: 26–47) patients received the surgery in 2020. Eight underwent cord autotransplants (SCI levels: T2 up to T11) and five peripheral nerve grafting (SCI levels: T10–L2).

PROCEDURE: After positioning the patients in the prone position, general anesthesia was induced. The skin and muscles overlying the thoracic and lumbar spinal column were incised. A laminectomy was performed at spinal cord injury level with a cutting ultrasonic scalpel (BoneScalpel®, Misonix, USA) to expose the dura mater, which was then cut open to expose the spinal cord. The cord autotransplant was performed (see Fig. 1A and 4(1/2)). The SCI epicenter was removed leaving a gap between two fresh spinal cord stumps and sent out for histological assessment. After measuring the gap, a hemicord segment of equal length along with the spared posterior spinal artery (PSA) was gently split from the rest of the cord either rostrally or caudally (depending on the level of SCI) and turned over to bridge the gap. The PSA ensured

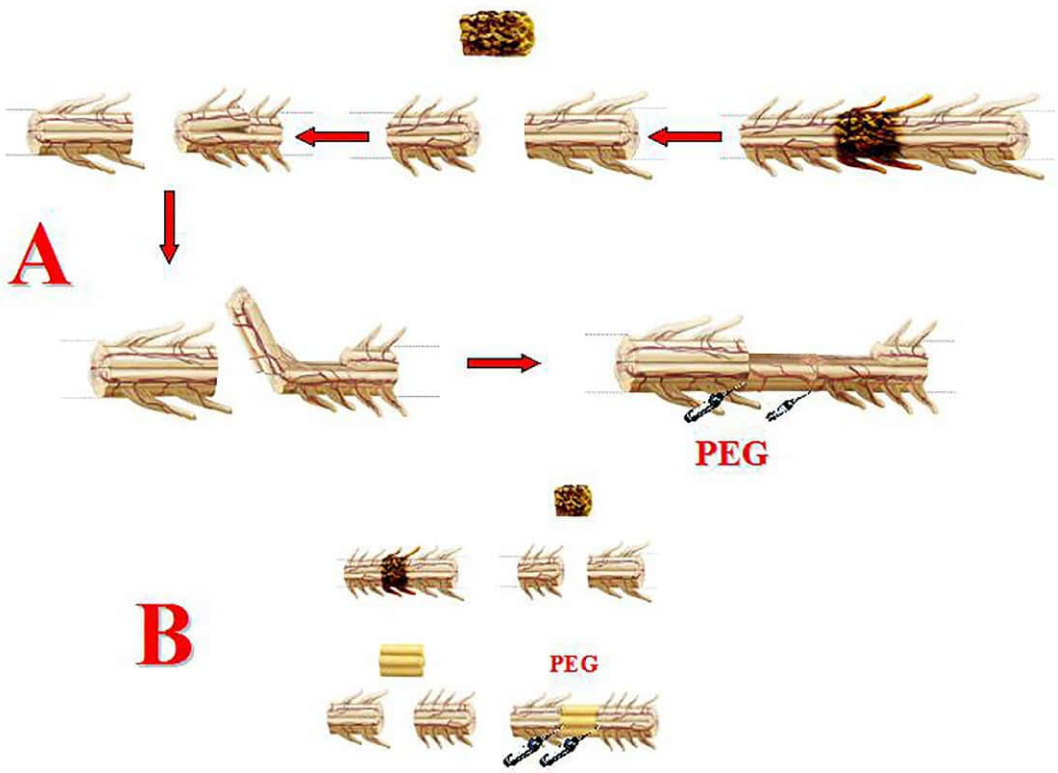

FIG. 1 (A) Modified Shirres-GEMINI protocol: surgical technique. The spinal injury epicenter, as assessed radiologically and then visually during surgery, is removed *en bloc*, leaving a gap bordered by undamaged cord ends. A pedicled (vascularized) hemicord of adequate length is split along the sagittal plane and subsequently turned over to fill the gap. PEG is applied at this moment at both ends. After dural closure with a graft, electrical stimulators are stitched onto the dura. (B) Whenever an autograft is not possible, a bundle of segments from the patient's own sural nerve is positioned inside the gap.

continual vascularization of the cord bridge. At the points of contact between the cord transplant and the stumps PEG600 (10 mL, Sigma-Aldrich/Merck, Germany) was topically injected. Finally, the dura mater was sutured with an artificial dural patch (Guanhao Biotech, China). A 3-hole silicone drainage tube was placed into the wound, and the wound was sutured by layers.

Whenever a cord autograft was not feasible (distal thoracic and lumbar), *free sural nerve transplantation (FSNT)* was performed. The skin and subcutaneous fat overlying the sural nerve of one leg were incised and the sural nerve excised and split into several segments of the same length, which were then assembled into one bundle. The spinal cord was exposed and treated similarly to the PCAT protocol (Fig. 1B). The sural nerve bundle was inserted into the gap and sutured under the operating microscope with 7–0 threads; PEG600 (10 mL) Sigma-Aldrich/Merck, Germany) was topically applied at the two bridge-stump interfaces.

Spinal cord stimulation employed four MEDTRONIC (USA) Model 3778 Pisces-Octad electrodes positioned to cover the two fusional interfaces (Fig. 4(3)). These were initially positioned in the last patients of this series and will be installed in all future patients.

The entire operation (both versions) took about 4 h to complete. Somatosensory evoked potentials (SEP) and motor evoked potentials (MEP) were recorded at preoperatively and 5 min, 1, 2, 3, 4 weeks postoperatively and analyzed with NIM-ECLIPSE® System (Medtronic, USA). All patients were scanned with MRI and DTI using a 1.5 T MRI system in the supine position preoperatively and at 4 weeks postoperatively. Post-operative spinal angiography is a consideration to assess graft vascularization, but possible toxicity from the contrast medium limits its use to selected cases.

Two weeks after surgery, rehabilitation began employing either an assistive robotic exoskeleton (AiWalker, Beijing Ai-Robotics Technology Co. Ltd., China) 30 min *bid*, or an intelligent auxiliary mobile robot (BangBang, Shanghai Bangbang Robot Co. Ltd., China) or a paraplegic standing frame, 40 min *bid*, or a rehabilitation bicycle 1 h *bid*.

PRELIMINARY RESULTS: The postoperative period was uneventful in all cases (no fever, incisional infections, or cerebrospinal fluid leaks). No adverse reaction of any kind to PEG600 was observed. Immunohistochemistry evinced complete

TABLE 1 cBBB scores of four female Beagles submitted to the modified Shirres-GEMINI variant.

Days	Transplant +PEG				Mean
−1	19	19	19	19	19
0	0	0	0	0	0

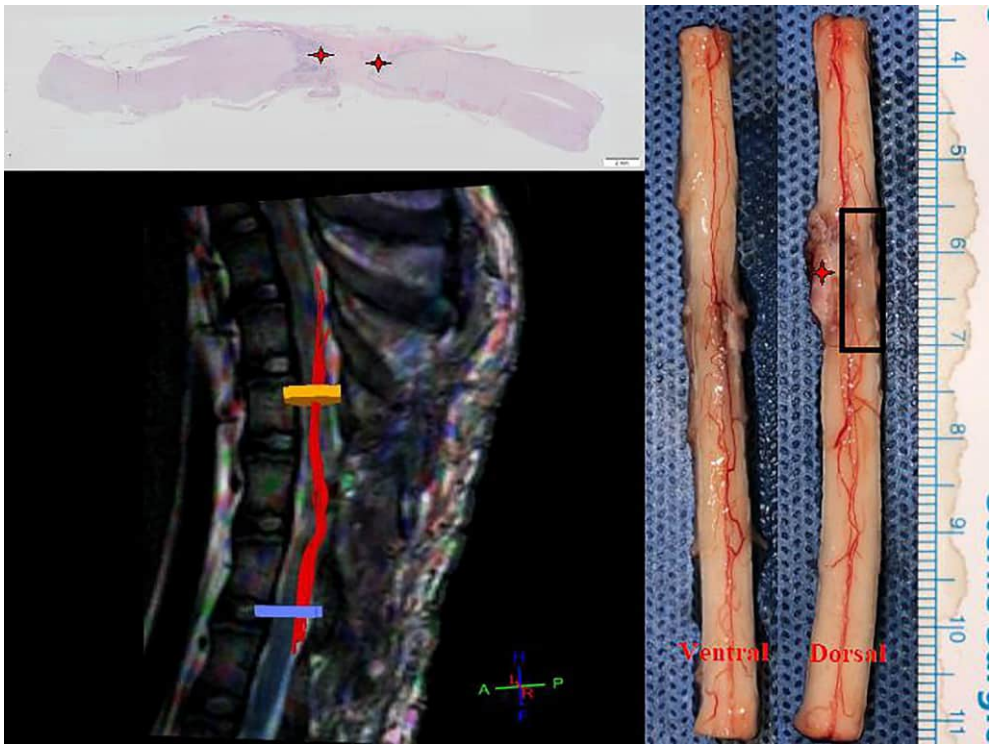

FIG. 2 Canine trial of the modified Shirres-GEMINI variant. Left upper half: sagittal view of the grafted cord (H&E staining): notice the absence of cysts at the points of fusion (stars). Right half: autoptic view of the cords: notice the graft perfectly enmeshed with the healthy cords (black rectangle); on the side, the hemigap is filled by scar. Left lower half: Diffusion Tensor Imaging (DTI) image at 6 months: new fibers extend beyond the fusional interfaces of the graft.

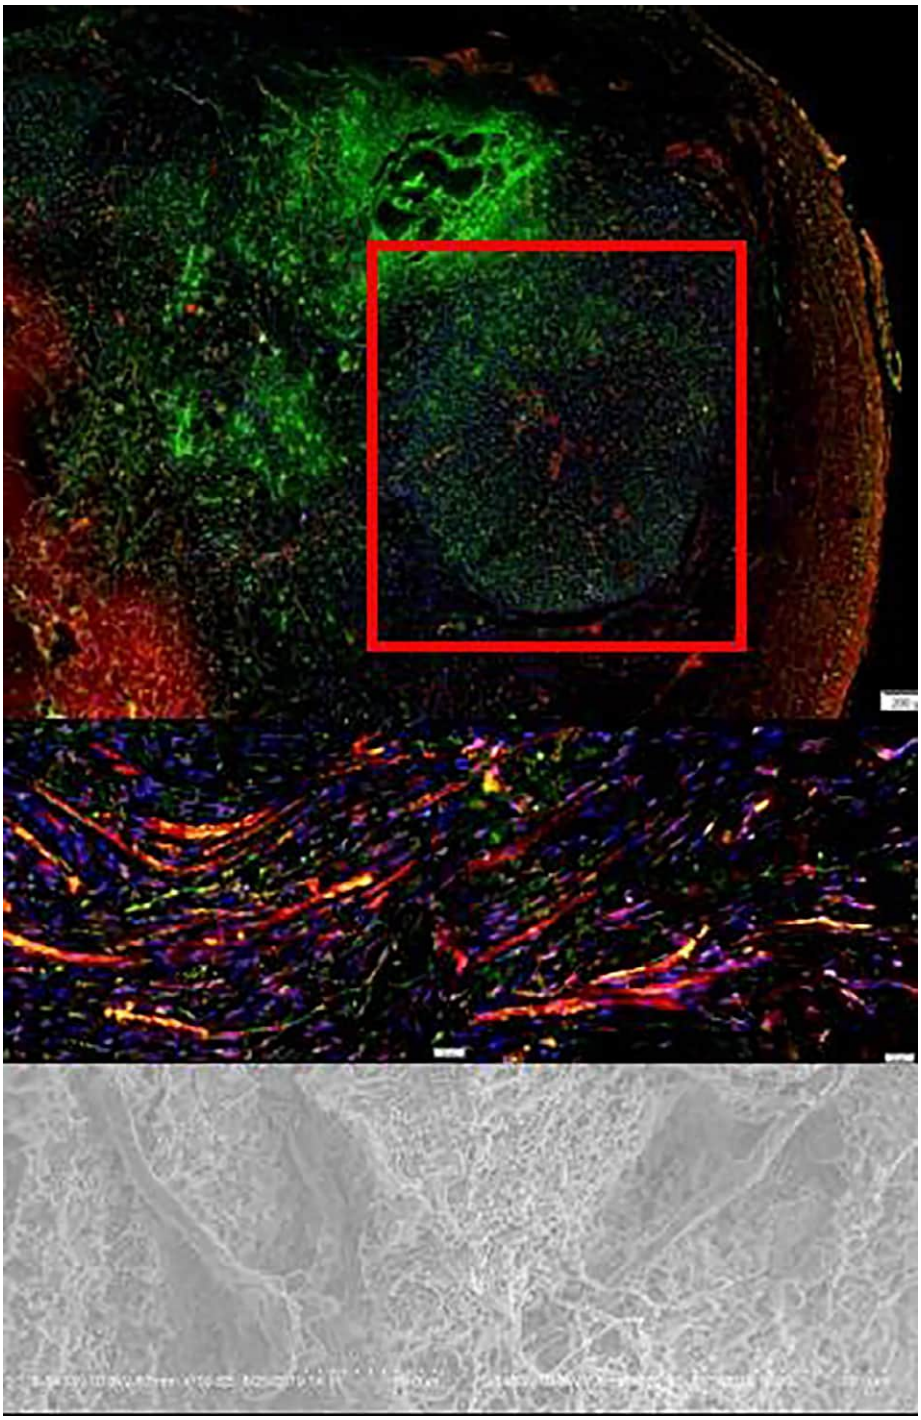

FIG. 3 Canine trial of the modified Shirres-GEMINI variant. Neurofilament immunofluorescence of the graft (red square) and fusional interfaces (middle): notice profuseness of fiber regrowth. Lower third: Scanning Electron Microscope images of sprouting fibers across the fusional interfaces.

absence of surviving fibers in the removed injured segment and correct removal of all damaged tissues. In line with the canine study, no sign of motor recovery was evinced for several days after the surgery. In patients treated with PEG only, the first signs of recovery were visible at 2 weeks, as one cord-transplant patient was able to move the knee, ankle and toe joints of both lower extremities voluntarily; a nerve-bridge patient did the same at 3 weeks. By month 4, several patients displayed voluntary control of the legs; initial supported ambulation was observed in some cases (Fig. 5). DTI and MEPs showed anatomical and physiological recovery (Fig. 5).

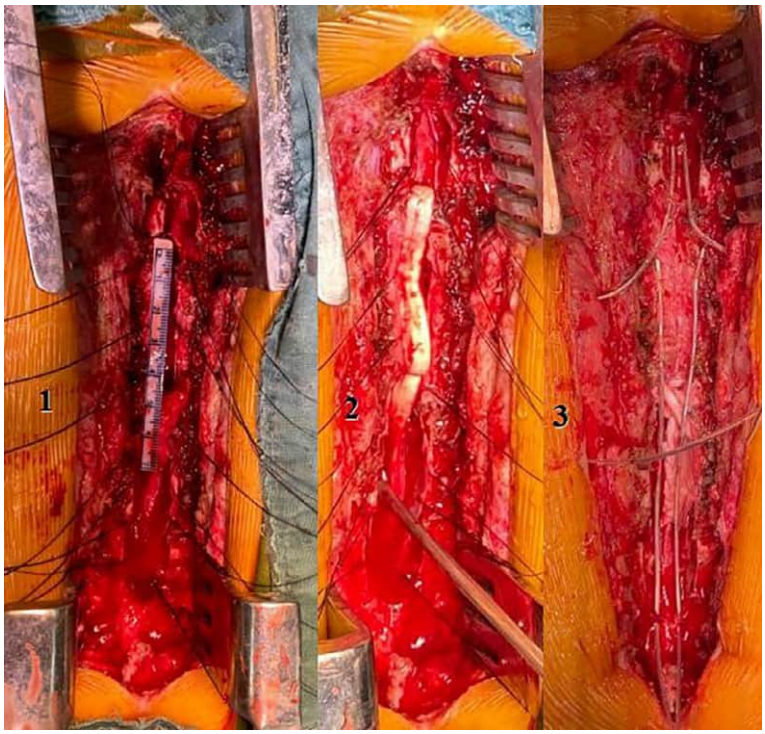

FIG. 4 Shirres-GEMINI operative view in a patient. Post-resection gap (T6–7), length: 5 cm (1); pedicled hemisegment in place (2); four MEDTRONIC octopolar leads are positioned on the dural graft (3).

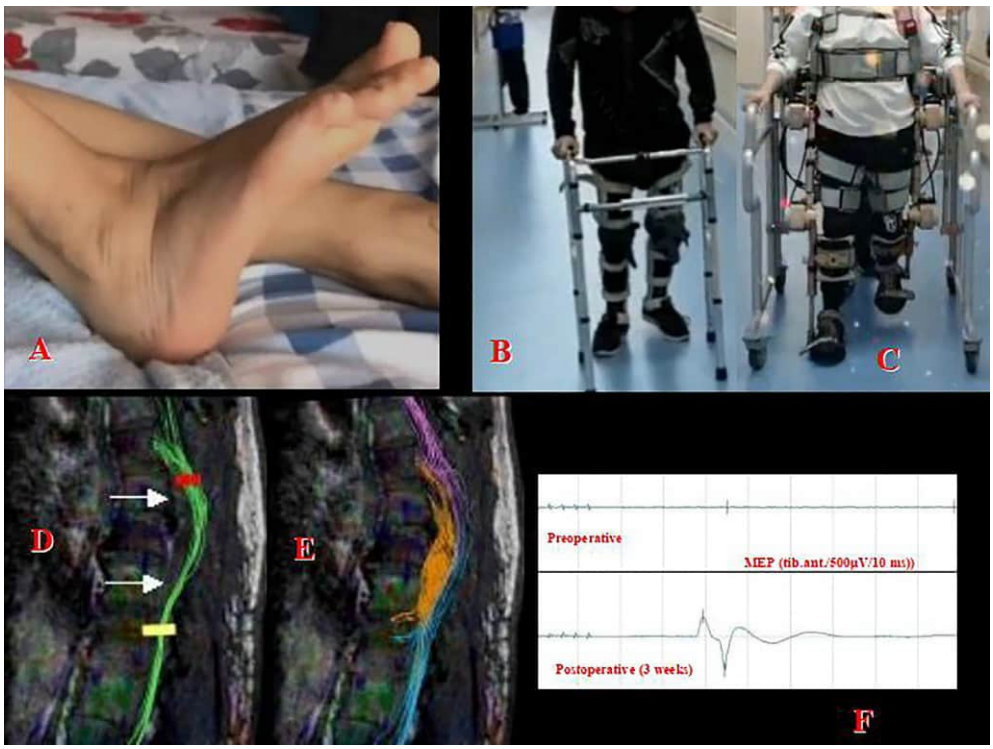

FIG. 5 Evidence of motor recovery in patients. (A) At 1 month, lower limbs can be flexed voluntarily. (B) At 2 months, patients can take the first steps with assistance. (C) Patient undergoing rehabilitation inside a robotic harness. (D and E) DTI showing fiber regrowth across the cord autograft. (F) Recovery of motor evoked potentials.

Spinal cord stimulation was conducted by stimulating with either the upper or the lower electrodes or combined. After a few weeks, stimulation with the upper electrodes could elicit motor activity in the legs, proving the viability of the anatomical bridge; patients experienced voluntary control over the legs at high voltage (5–9 V). As expected, stimulation with the lower electrodes activated leg movements immediately after the surgery, again at high voltages. Combination stimulation was carried out at low voltage (3 V) cranially and high voltage caudally (max 9 V). Frequencies assessed ranged from low (20 Hz) to moderately high (60 Hz); pulse widths were tested between 60 and 450 μs. Preliminary observations suggest that electrical stimulation does indeed accelerate recovery.

Conclusion

The decades-old idea that SCI can be cured by removing the most heavily damaged segment of a cord and bringing the healthy tissue above and below the epicenter in direct—or indirect contact, through a viable graft/transplant (either cord or peripheral nerve segments)—is now being translated clinically on the heels of the introduction of the GEMINI spinal cord fusion protocol in 2013. The initial results of the first clinical trial of GEMINI-powered spinal cord autografting are promising.

Applications to other areas of neuroscience

In this chapter, we have reviewed the GEMINI spinal cord fusion protocol in its translation to spinal cord injury. The GEMINI protocol exploits fusogens such as polyethylene glycol (PEG) and spinal electrical stimulation to re-start nerve conduction across transected spinal cords. Animal studies including in rodents, canines, and primates confirmed its efficacy. The GEMINI protocol has been developed to enable head and brain transplants. Head transplants are now been assessed in man, while brain transplants are in the experimental phase. Both have been developed primarily for life extension, and once tolerogenic protocols that avoid immunosuppression become available, they will revolutionize human society as we know it. Cosmetic body transplants will also become an option. The GEMINI protocol can theoretically be applied to several neuroconditions, e.g., multiple sclerosis, in which focal damage in the cord is primarily responsible for motor disability. Transplanting segments of healthy cords could reverse arm and gait impairment. The availability of a powerful nerve function restoration protocol can actually be envisioned as a treatment for several brain ailments. For instance, a possible scenario deals with transplantation of segments of healthy brain (from donor, fresh cadavers, or organoids) as replacement of diseased brain tissue, e.g., after stroke or major trauma, including prolonged unconsciousness states.

Mini-dictionary of terms

1. PEG: Polyethylene Glycol is a widely used chemical with membrane fusogenic properties. Once applied, it leads to the reconstitution of damaged cell membranes.
2. Spinal Cord Electrical Stimulation: this is a widely employed technique to control chronic pain, with the additional benefit of kick-starting depressed neural activity in the cord movement generating centers after spinal injury.
3. GEMINI: this is the technology that re-establishes anatomophysiologic continuity of a transected spinal cord. It combines fusogens and electrical stimulation of the nervous system.
4. Shirres-GEMINI approach: this surgery combines *en bloc* removal of the most injured segment of the cord, replacement with a pedicled hemicord segment from above or below the extirpation area and application of the GEMINI spinal cord fusion protocol at both ends of the grafted segment.
5. Freeman-GEMINI approach: this surgery combines en bloc removal of the most injured segment of the cord, shortening of the vertebral column and direct fusion of the stumps under GEMINI conditions.

Key facts of the GEMINI spinal cord fusion protocol for spinal cord injury

1. GEMINI was introduced with the goal of enabling head and brain transplants in 2013
2. GEMINI exploits special substances called fusogens, such as polyethylene glycol (PEG) combined with spinal electrical stimulation to force two ends of a transected cord to re-establish communication.
3. Fusogens have the ability to refuse damaged cell membranes, including neuronal and axonal membranes.

4. Electricity stimulates nerve fiber regrowth and "powers up" depressed neuronal circuits after spinal cord injury.
5. The GEMINI spinal cord fusion (SCF) protocol has been shown to reverse motor paralysis after spinal cord transection in rodents, canines and primates

Summary points

1. There is at present no biological cure for chronic paralysis following spinal cord injury (SCI). Chronic disability after spinal cord injury remains challenge.
2. Many experimental treatments including stem cells have not led to a long-sought cure
3. In the 1940s to 1950s, surgeons believed that the first step toward a cure would require the extirpation of the most damaged segment of the cord. The result would be the creation of two undamaged stumps whose ends would have to be connected somehow.
4. The GEMINI spinal cord fusion protocol was introduced in 2013 to mend transected spinal cords in the context of head/brain transplants
5. By combining 3 and 4, a permanent, biological cure becomes: after removing the most damaged portion of the spinal cord *en bloc*, the two ends of the cord can be brought together after spinal (vertebral) shortening (Freeman-GEMINI approach) or alternatively, the post-extirpation gap is filled with a segment of normal cord (Shirres-GEMINI approach)
6. We describe these two approaches and report the preliminary results of the first clinical trial testing autologous cord grafting in chronic SCI patients.

Abbreviations

cABC I	chondroitinase ABC I
CNS	central nervous system
CS	chondroitin sulfate
CSPG	chondroitin sulfate proteoglycan
CSPGs	chondroitin sulfate proteoglycans
DS	dermatan sulfate
DSPG	dermatan sulfate proteoglycan
ECM	extracellular matrix
GAGs	glycosaminoglycans
GBM	glioblastoma
HA	hyaluronic acid
Hep	heparin
HepS	heparan sulfate
HS	heparin sulfate
KS	keratan sulfate
PEG	polyethylene glycol (PEG)
SCI	spinal cord injury

Molecular perspectives

Glycosaminoglycans and proteoglycans

Extracellular matrices (ECMs) and cell surfaces of the mammalian tissues contain repeating disaccharide units known as glycosaminoglycans (GAGs). These linear polysaccharides can be sulfated in various positions to obtain a negatively charged nature that is essential for molecular recognition and binding. The corresponding reactions are catalyzed by the enzymes of the sulfotransferase family. Based on the type of disaccharide units, GAGs are categorized into several groups, including hyaluronic acid (HA), chondroitin sulfate/dermatan sulfate (CS/DS), heparin/heparin sulfate (Hep/HS), and keratan sulfate (KS) (Gandhi & Mancera, 2008).

A typical chondroitin sulfate disaccharide unit in human, chondroitin-6-sulfate (C6S) with the primary configuration containing a uronic acid (Glucuronic acid) and amino sugar (Galactosamine) is shown in Fig. 1A. As shown in Fig. 1B; GAG chains can covalently bind at their reducing ends to a serine or asparagine residue of a target protein, forming a proteoglycan (Jackson, Busch, & Cardin, 1991). On a higher level, a biopolymer such as hyaluronic acid acts as a backbone structure to assemble similar or various types of proteoglycans (Fig. 1C).

These macromolecules are synthesized in all mammalian cells and based on the type and function; they may be secreted into the ECM, localized into the plasma membrane, or stored in secretory vesicles (Couchman, 2010; Dick, Akslen-Hoel, Grøndahl, Kjos, & Prydz, 2012; Iozzo & Schaefer, 2015; Yanagishita, 1993). Due to the wide variety of functions, any

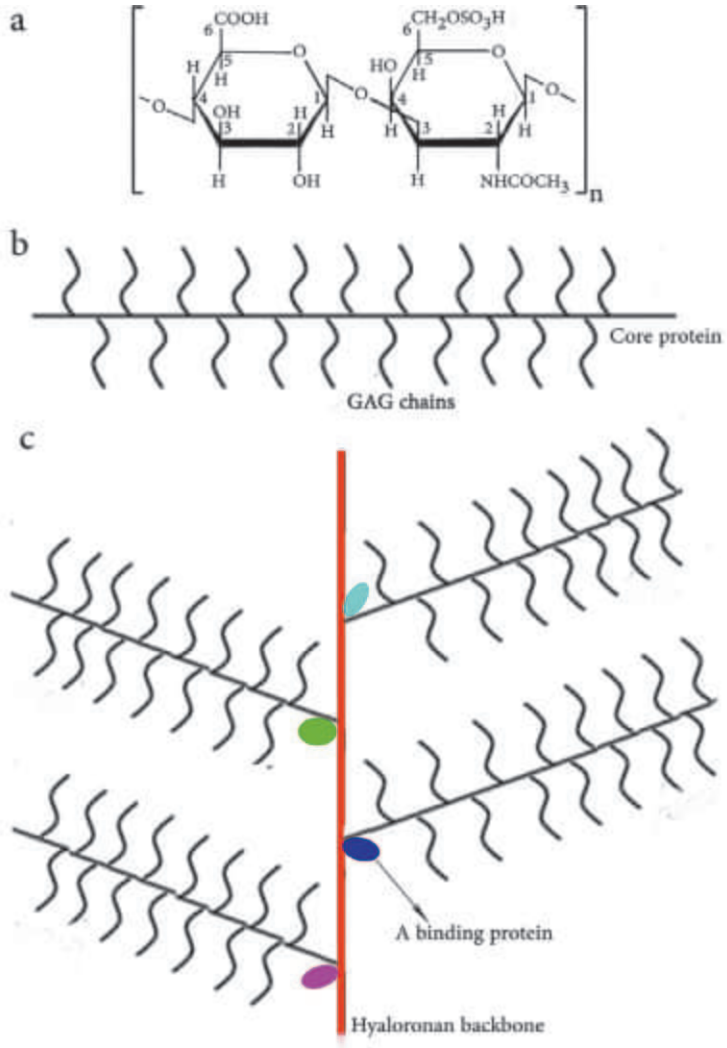

FIG. 1 Structural organization of Glycosaminoglycans and Proteoglycans. (A) The structure of a disaccharide unite in chondroitin-6-sulfate (C6S). D-glucuronic acid has a β1–3 linkage to *N*-acetyl-β-D-galactosamine. The connection between disaccharide units in the polymerized GAG is β1–4. Galactosamine can be variously sulfated at either 4 or 6 positions to give C4S or C6S, respectively. (B) The polymerized GAG chains are attached to the target protein forming a proteoglycan. The GAG chains may be the same or of other types. (C) The hyaluronic acid serves as a backbone to assemble similar or different types of proteoglycans. Specific proteins, such as growth factors and cytokines, can reversibly bind to this macromolecule.

defects in the synthesis and processing of proteoglycans have important clinical manifestations (Schwartz & Domowicz, 2018). Regarding the protein binding affinity and biocompatibility of GAGs, they are proposed as a tool for localized drug-delivery, using enzymes as drug (Hachim, Whittaker, Kim, & Stevens, 2019).

Distribution and functions of GAGs and proteoglycans

The GAGs play essential roles in fundamental biological processes, and wide distribution of these biopolymers in animals demonstrates that they have conserved functions in organisms (DeAngelis, 2002). In the normal state, individual tissues of the human body contain a defined combination of GAGs, some of which are tissue-specific, and others may be temporally observe during growth, development, and pathogenic conditions.

The ability to absorb water molecules and their spatial structure enables GAGs and proteoglycans to provide a suitable scaffold that is essential to maintain the shape, cohesive properties, and mechanical features of tissues (Beldowski, Mazurkiewicz, Topoliński, & Małek, 2019). Accordingly, in tissue-based diseases, damage to the structure of proteoglycan is a central event (Hardingham & Bayliss, 1990). Some of the GAGs can bind into several specific proteins such as

cytokines, chemokines, growth factors, morphogens, etc., to form biologically effective types of macromolecules (Imberty, Lortat-Jacob, & Pérez, 2007). These interactions are crucial in regulating of some critical biological processes, including cell migration (Merle, Durussel, Delmas, & Clézardin, 1999), regulation of blood coagulation and homeostasis (Bourin & Lindahl, 1993; Lasne, Jude, & Susen, 2006), growth factor control (Lander & Selleck, 2000), cell adhesion, and signaling (Werz & Schachner, 1988), inflammation (Gill, Wight, & Frevert, 2010), and pathogens attachment (García et al., 2016). They are involved in multicellular processes and have critical roles in development.

The GAGs are also involved in the inhibition of smooth muscle cell proliferation (Clowes & Karnowsky, 1977). It has been reported that proteoglycans may have essential roles in normal glomerular cell function and progressive renal disease (Templeton, 1992). They are considered as the first defensive line at the bladder's luminal surface against urinary tract infections, that created by pathogenic *Escherichia coli* among postmenopausal women (Anand et al., 2012). It has postulated that the accumulation of specific GAGs may form a physical barrier to the passage of immunocompetent cells from the mother to the fetus (Calatroni & di Ferrante, 1969). The changes in the composition and molecular structure of placental GAGs during pregnancy could alter the molecular transport rate through placental connective tissue and affect the rate of fetal growth (Lee, Jamieson, & Schafer, 1973). It has been reported that GAGs are involved in tumor development, angiogenesis and metastasis in certain types of cancers (Muir, De Winter, Verhaagen, & Fawcett, 2019).

CSPGs in the nervous system

It has revealed that CSPGs and DSPGs are dominant proteoglycans in CNS-ECM (Iozzo & Schaefer, 2015). Chondroitin sulfate proteoglycans (CSPGs) are those CS-GAGs that are covalently linked to a core protein (Imberty et al., 2007). The GAG side chains in CSPGs are of different lengths, and the disaccharide units of CSPGs have either *N*-acetylglucosamine or *N*-acetylgalactosamine as well as uronic acid (see Fig. 1). Hence, depending on the length and the type of disaccharide unit and the position of sulfate moiety (positions 4 or 6), different types of CSPGs have identified, some of them have important tasks in CNS (Quraishe, Forbes, & Andrews, 2018). In CNS-ECM, various types of CSPGs bind to linear non-sulfated polysaccharides such as hyaluronan to produce a specific combination of proteoglycans, which is collectively known as lectican family proteoglycans. They include Neurocan, Brevican, Aggrecan, Perlecan, Testican, Versican, and Biglycan (Jones, Margolis, & Tuszynski, 2003; Siebert, Conta Steencken, & Osterhout, 2014). Some of the GAGs are attached to the transmembrane proteins and form the transmembrane family of proteoglycans. A schematic representation

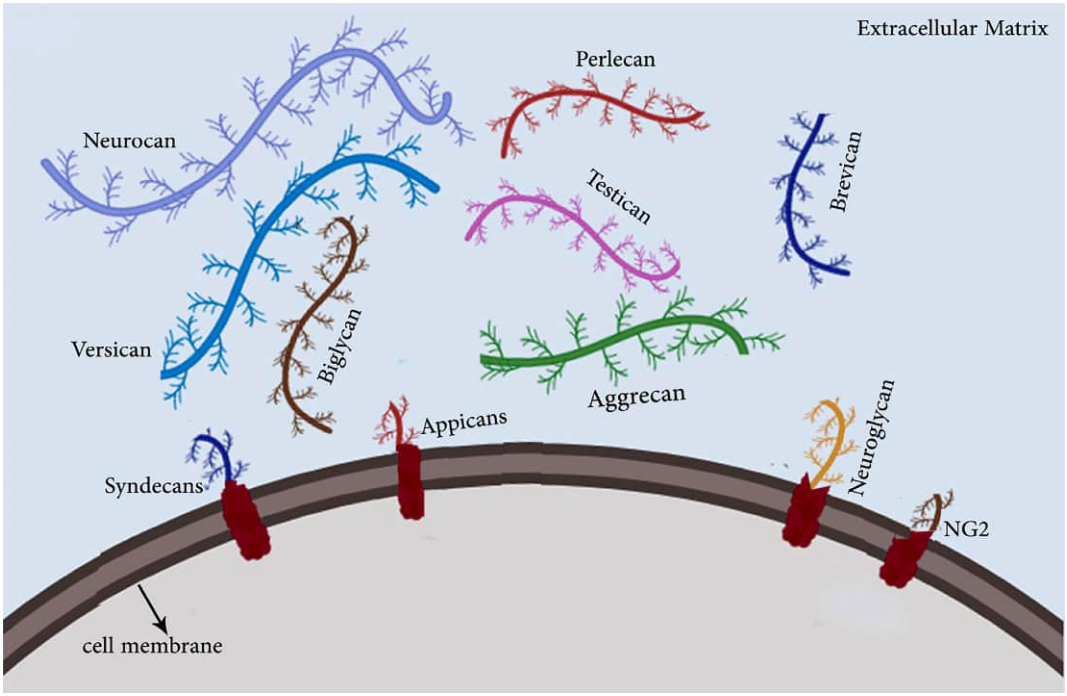

FIG. 2 A schematic representation of the proteoglycan families found in the extracellular environment and the membrane of the central nervous system. The proteoglycans in the extracellular matrix of central nervous system (CNS) including, Aggrecan, Versican, Neurocan, and Brevican, are members of the Lectican family. Members of syndecan family along with Apican, Neuroglycan, and NG2 are transmembrane proteoglycans.

of various proteoglycans in the cell surface and ECM of nervous tissues is provided in Fig. 2 (Schwartz & Domowicz, 2018). Structurally, the CNS-ECM proteoglycans provide the viscoelastic properties, maintain ions and water content and normal osmotic pressure, and dictate proper tissue organization. It has shown that the development of the nervous system in mammals involves coordinated cellular interactions, such as patterning and routing of migrating neural cells, axon pathfinding, and synapse formation, that is due to the proper organization of the nervous ECM (Silver & Silver, 2014; Tessier-Lavigne & Goodman, 1996). Hence, the time-dependent concentration of CSPGs relative to other adhesive matrix molecules at the various developmental stage, define the normal state of the CNS-ECM (Galtrey & Fawcett, 2007).

Implication of CSPGs in pathogen conditions

It has been reported that CSPGs have implications in the processes of tumor metastasis by affecting endothelial migration and adhesion (Denholm, Lin, & Silver, 2001). In the case of brain cancer, changing the pattern of interaction of CS with ligands, growth factor receptors, extracellular matrix components, and structural proteins is accompanied by the progress of Glioblastoma (GBM) (Wade et al., 2013). It has also revealed that neurodegenerative disorders are related to defects in the synthesis/degradation of proteoglycans that affect the structural integrity of nervous tissues (DeWitt, Richey, Praprotnik, Silver, & Perry, 1994). Genome-wide association studies have shown that mental disorders such as bipolar character and depression are related to unbalance in CNS-ECM constituents (Cichon et al., 2011; Shi et al., 2011).

One of the important clinical manifestations after SCI includes the rapid increasing of various types of CSPGs in ECM. It is believed that this event is a defensive mechanism that seals off the injury to prevent bacterial penetration. The corresponding injury response in damaged CNS is called reactive gliosis or glial scarring (Fawcett & Asher, 1999). The glial scar also has other positive effects such as reducing the inflammation area, modulating immune activity, and helping to restore the blood–brain barrier (Lin, Kwok, Crespo, & Fawcett, 2008; Rolls, Shechter, & Schwartz, 2009; Tuinstra, Ducommun, Briley, & Shea, 2013). However, despite these positive impacts, the glial scar as a physical barrier reveals a negative role in axonal regrowth, sprouting, and synaptic reorganization following SCI (Cregg et al., 2014; Siebert et al., 2014). Production of CSPGs occurs after the cute phase in approximately 48 h following SCI (Katoh, Yokota, & Fehlings, 2019). It also prevents oligodendrocyte maturation and remyelination (Karus et al., 2016). Accordingly, medical intervention to control the concentration of CSPGs and limit the scar size in CNS-ECM has become central to the treatment of spinal cord injuries, and management of the CSPGs concentration during this period can result in the successful treatment of SCI in subsequent phases. There are numerous reports that carbohydrate and proteoglycan degrading enzymes can be used as a therapeutic drug to prevent CSPGs chains from accumulating in the site of SCI (Bradbury et al., 2002; García-Alías, Barkhuysen, Buckle, & Fawcett, 2009; Rosenzweig et al., 2019; Tauchi et al., 2012).

Glycosaminoglycan degrading enzymes: A brief description

Regarding the various functions of GAG-proteoglycans, it is evident that creating a delicate balance between the biosynthesis and degradation of heteropolysaccharides is crucial in maintaining the normal health conditions of tissues. As mentioned in Implication of CSPGs in pathogen conditions section, the formation of proteoglycan-rich glial scar around traumatic injury of SCI inhibits long-term axonal recovery predominantly by CSPGs moieties, and degrading enzymes is considered as therapeutic drugs to overcome this medicinal challenge. Two types of enzymes can depolymerize GAG chains including lyases (EC 4.2.2.-) and hydrolases (EC 3-2-1.-). The lyases degrade GAGs by eliminative cleavage, while hydrolases-based degradation is carried out by hydrolytic cleavage. Based on the position of the cutting site, the pattern of enzymatic action is exolytic or endolytic mode (Linhardt, 2001) (Ernst, Langer, Cooney, & Sasisekharan, 1995). In vivo degradation of GAGs is carried out by corresponding hydrolases such as keratinase, hyaluronic acid hydrolase, and heparin hydrolase. The GAG degrading lyases have mainly bacterial sources, and are categorized into three main groups, including heparinases, chondroitinases, and hyaluronidases.

Structural features of chondroitinase ABC I

According to CAZy (Carbohydrate-Active enZYmes Database), the tertiary structure of cABC I include $(\alpha/\alpha)_6$ toroid + anti-parallel β-sheet. As shown in Fig. 3, it is composed of three distinctive domains, including N- and C-terminals, that are symmetrically attached to the central (catalytic) domain (Huang et al., 2003). The catalytic residues are located in the central domain, and include His-501, Tyr-508, Arg-560, and Glu-653 (Prabhakar et al., 2005). The peripheral domains are mainly made up of well-defined organized β-sheets, and the central domain has mainly helix conformation. The movement of N- and C-terminal domains around the catalytic region leads to the creation of open and closed conformation that is

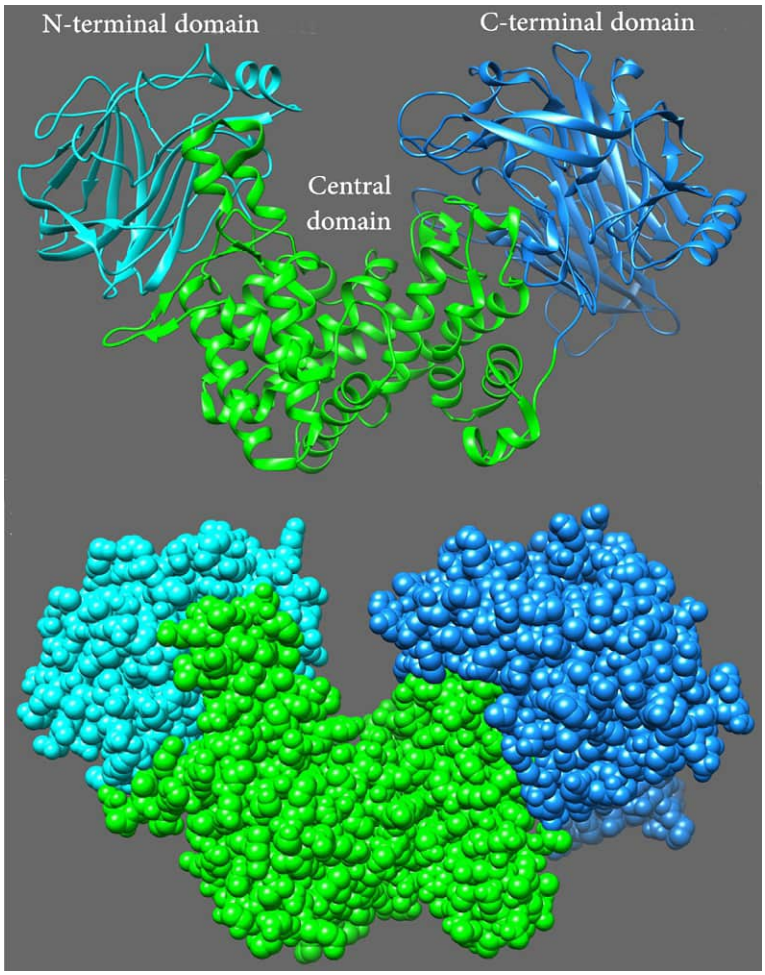

FIG. 3 The Tertiary structure of chondroitinase ABC I. Ribbon (Upper panel) and sphere (lower panel) representation of cABC I. The structure was depicted by the UCSF Chimera program using the crystal structure of cABC I (PDB ID:1HN0).

essential for the catalytic activity of the enzyme. The enzyme cleaves its substrates at the glycosidic bond via β-elimination of 1,4-hexosaminidic bonds to produce Δ4,5-unsaturated disaccharides, and a reducing end polysaccharide. Spectroscopically, product formation can be monitored as an increase in absorbance at 232 nm as a function of time.

Chondroitinase ABC I and spinal cord injury

By convention, A, B, and C in chondroitinase ABC (cABC) nomenclature, refers to chondroitin 4-sulfate, dermatan sulfate, and chondroitin 6-sulfate, respectively. According to BRENDA—The Comprehensive Enzyme Information database (www.brenda-enzymes.org), cABC I from *Proteus vulgaris* (EC 4.2.2.20) is a broad specific endolytic enzyme that degrades a variety of glycosaminoglycans of the chondroitin-sulfate- and dermatan-sulfate type. It can also acts on hyaluronan at a much lower rate. Fortunately, these substrates are the main constituents of CNS GAGs that are formed by activated astrocytes following SCI. Hence, the broad specificity of cABC I toward a combination of GAGs can be considered as a positive feature to degrade the GAG chains and can restore the right condition for nerve regeneration following SCI.

In vivo delivery of cABC I to reduce the size of glial scar and removing the inhibitory environment for the treatment of SCI was first reported by Lemons et al. in 1999 (Lemons, Howland, & Anderson, 1999). Four years later, research groups from the University of Cambridge and the University of London delivered cABC to the lesioned dorsal columns of adult rats and observed a marked functional recovery of injured CNS (Bradbury et al., 2002). To analyze the effects of cABC on axon regeneration, Lin and co-workers made unilateral nigrostriatal lesions in adult rats and found that injection of cABC can

digest hyaluronan and reduce neurocan in a limited area around the injection region. At the same time, the majority of GAGs are inaccessible to cABC digestion. They suggest that a single injection of cABC can produce an environment conducive to CNS repair for a long-term over 10 days (Lin et al., 2008). In 2011, Fawcett et al. showed that using cABC combined with rehabilitation is effective in functional recovery of forelimb function in rats with chronic SCI. They used cABC I 4 weeks after SCI (Wang, Ichiyama, Zhao, Andrews, & Fawcett, 2011). These studies, together with other investigations, have confirmed the ability of cABC I to help axon regeneration following SCI (Kasinathan, Volety, & Josyula, 2016; Muir et al., 2019).

Chondroitinase ABC I for enzyme therapy: Challenges and perspectives

Proteus Vulgaris as the bacterial source of cABC I presents in soil and intestinal tract of the human body. It uses acidic polysaccharides along with epithelial cells in the intestinal lumen as its nutrient source. Accordingly, its optimum temperature for the activity is in accordance with the normal temperature of the human body. However, the time-dependent concentration of cABC I in *P. vulgaris* is low, which is essential for its solubility. In other words, protein aggregation is an entropy-dependent process, and increasing the concentration of the enzyme molecules for practical uses, particularly at 37 °C, leads to protein aggregation due to the higher probability of effective molecular collisions (Mohammadyari, Shirdel, Jafarian, & Khalifeh, 2019). Additionally, the enzyme adaptation has been occurred not only on the temperature but also on the other environmental factors of *P. vulgaris* such as pH and ionic strengths that are different from those found in the new therapeutic environment. Accordingly, changing the environmental conditions for the enzyme is accompanied by decreasing its half-life and lower catalytic efficiency due to its low conformational stability. So, more concentration of the enzyme is needed to have efficient catalysis. Nonetheless, as mentioned above, there is a critical concentration of the enzyme above that it undergoes molecular aggregation. Moreover, using a high concentration of the recombinant enzyme per injection or increasing the number of enzyme injections at the site of SCI for more efficient catalysis may have immunogenicity responses (Muir et al., 2019). Considering the instability of cABC I due to protein aggregation and decreased half-life as well as medical challenges following repeatedly administer of the recombinant enzyme, various enzyme stabilization and enzyme delivery methods, should be developed to efficient use of the enzyme for SCI treatment. Furthermore, the formulation of the enzyme appropriate for long-term storage permits the clinicians to access the enzyme in the shortest time and a usable form.

Protein engineering strategies toward functional drug delivery

The enzyme can be synthesized, extracted, and purified with the enzyme technology methods. The classical procedures for enhancing the enzyme stability involve setting up right environmental conditions using suitable solvents containing various types of osmolytes and additives as stabilizers. It was shown that chemical modification of the recombinant enzymes with Polyethylene glycol (PEG) could increase the protein half-life and reduces the possibility of immunological side effects due to its bacterial origin (Greenwald, 2001). Additionally, site-directed mutagenesis has intensively used to logically replace critical amino acids on the structure of the protein with new residues to improve the functional and structural features of the enzyme. For example, it was revealed that increasing the repulsive electrostatic interactions between enzyme molecules via changing of surface-exposed residues by site-directed mutagenesis can reduce aggregation (Mohammadyari et al., 2019). Shoichet et al. used PEG-chemical modification procedure and site-directed mutagenesis strategy to produce improved engineered enzyme for SCI treatment. They demonstrated that representative PEGylated mutants of cABC could be locally delivered at the site of SCI in a more stabilized form (Hettiaratchi et al., 2019). Drug nano-carriers such as nano-structured lipid carriers (NLCs) are also potential candidates for the efficiently deliver of the enzyme toward its target. Enzyme immobilization using biocompatible nano-structures can protect the enzyme molecules from biodegradation and leads to the gradual release of the enzyme (Xia et al., 2015; Zuidema, Gilbert, & Osterhout, 2016). These are only examples of ongoing research studies on the humanization and methodological setting for using cABC I as a drug. Details of such studies have been reviewed elsewhere (Kasinathan et al., 2016; Muir et al., 2019).

Combinatorial therapy with chondroitinase ABC I

It is worth mentioning that SCI is accompanied by several events including proliferation of astrocytes, accumulation of macrophages and microglia, production of growth-inhibitory matrix around SCI region, abnormality in signal transduction, etc. These phenomena result in multiple clinical consequences. Therefore, SCI should be simultaneously targeted with various medical interventions (Rolls et al., 2009). In other words, cABC I should be used besides other therapeutic agents

to achieve a satisfactory outcome. Efficient delivery of cABC as a drug requires the determination of the therapeutic window of enzyme utilization during treatment time. As well as timing, the threshold of enzyme concentration influences the efficacy of enzyme therapy. It was shown that the expression of corresponding proteins increases following SCI within the first 24 h, and the maximum level of CSPGs is generally observed approximately 2 weeks after SCI. However, the gradual increase of CSPGs over time is occurred with different rates according to the type of proteoglycan (Jones et al., 2003). Finally, locomotor recovery depends on optimized drug-based treatments combined with rehabilitation.

Applications to other areas of neuroscience

Regarding the diverse roles of CSPGs in the physiological and pathological conditions of the CNS-ECM, cABC I can be used to control the right composition of the CSPGs according to the abnormal states of the nervous tissue. It had demonstrated that the efficiency of nerve recovery through peripheral nerve graft (PNG) increased in combined with cABC I and acidic fibroblast growth factor usage (DePaul, Lin, Silver, & Lee, 2015). The enzyme can also be used to eliminate the inhibitory function of CSPGs on the remyelination, which is essential in the treatment of multiple sclerosis (Lau et al., 2012). Investigating the experimental models has revealed that cABC I offers the opportunity to improve the outcome of Alzheimer's disease treatment via restoration of extracellular matrix plasticity in the synaptic region of hippocampal (Végh et al., 2014). It would be beneficial in the case of Parkinson's disease and for patients that are involved in phobias and anxiety (Moon, Asher, Rhodes, & Fawcett, 2001; Thompson et al., 2018). There are pieces of evidence that cABC I is helpful in the treatment of glioblastoma through sensitizing the glioblastoma cells to cancer drugs and enhancing the spread of oncolytic viruses as well as changing the pattern of the interaction of CSPGs with specific proteins (Dmitrieva et al., 2011; Jaime-Ramirez et al., 2017; Wade et al., 2013).

Mini-dictionary of terms

Glycosaminoglycan: Linear polysaccharide made up of repeating disaccharide units. Based on the type of sugar building blocks, various glycosaminoglycans are found in extracellular matrices of tissues.

Proteoglycan: A highly glycosylated protein produced by attachment of a given glycosaminoglycan to a given target protein. A combination of various types of proteoglycans is found in extracellular matrices. The time-dependent concentration of proteoglycans is changed due to the developmental stage or pathogenic conditions of the cells and tissues.

Chondroitin sulfate proteoglycans: Specific types of proteoglycans that are sulfated in representative positions of their sugar moiety. They are one of the main constituents of the extracellular matrix of the nervous system.

CAZy: stands for "Carbohydrate-Active enZYmes Database." It is the specialized database that describes the families of structurally-related enzymes and carbohydrate-binding modules that are involved in the breakdown, biosynthesis, or modification of carbohydrates and glycoconjugates. It can be found at http://www.cazy.org/

BRENDA: It is a bioinformatics database containing the functional and structural information of the known enzymes. It can be found at www.brenda-enzymes.org

Glioblastoma: A type of cancer originated from the proliferation of astrocytes in the brain or spinal cord.

Conformational stability: In statistical thermodynamics, the conformational stability of a given enzyme refers to the ratio of the population of the native structure to denature states of the enzyme molecules at equilibrium condition. When a single molecule is considered, it is the structural integrity of an enzyme molecule that is the difference energy of the unfolded and folded states of an enzyme molecule. In both paradigms, increasing conformational stability leads to the activity improvement of the enzyme.

Catalytic efficiency: The minimum concentration of the substrate molecule required for an enzyme to reach its maximum catalysis capacity.

Half-life: The time required for an enzyme to lose 50% of its original activity. Increasing the conformational stability leads to increasing the half-life of an enzyme.

Protein Aggregation: is a process in which protein molecules accumulate and form molecular aggregates. Upon aggregation, the protein loses its activity. It occurred by attractive intermolecular interactions, mainly the hydrophobic one, between surface-exposed hydrophobic patches. Based on the identity of hydrophobic interaction, protein aggregation depends on the molecular collisions, which enhance by increasing the temperature and the concentration of the protein molecule. Proteins with surfaced-exposed hydrophobic patches are more prone to aggregation.

Domain: In protein science, domain is defined as distinct structural unite in the three dimensional structure of proteins. In the simplest form, the whole structure of a small and compact protein is considered as a domain. Some proteins have two

or more domains. Domains are responsible for the structural integrity and stability of proteins. They are also involved in the functional features of the proteins.

Recombinant DNA technology: Recombinant DNA technology includes insertion of a given DNA sequence from an organism to the other one. In protein engineering studies, the host organism may be an engineered bacterium that is used for the expression of a recombinant protein which is of value to biotechnology.

Key facts of chondroitinase ABC I

Chondroitinase ABC I is a non-hydrolytic degrading enzyme that cleaves the glycosidic bonds of polysaccharides.

- It has three distinctive domains, where the peripheral ones are symmetrically arranged around the central catalytic domain.
- Naturally, this enzyme is expressed in *Proteus Vulgaris*. This bacterium is found in soil and intestinal tract of the human body.
- The enzyme and its mutated variants can be produced by recombinant DNA technology, and using engineered bacteria as protein express systems.
- Chondroitinase ABC I as a polysaccharide lyase has broad substrate specificity.
- Its substrates constitute the main glycosaminoglycans of extracellular matrix of the central nervous system.

Key facts of the therapeutic potential of chondroitinase ABC I

- The concentration of corresponding substrates of chondroitinase ABC I increases in the extracellular matrix upon spinal cord injury, which acts as inhibitors against axon regeneration.
- The enzyme can be used to degrade the glycosaminoglycans around the traumatic region of the spinal cord.
- Its conformational stability and half-life reduce in the environmental conditions around the region of SCI.
- To use as a drug, the conformational stability, and biocompatibility of the enzyme should be increased via protein engineering strategies.
- Appropriate drug delivery methods should be developed to efficient use of chondroitinase ABC I at the site of spinal cord damage.

Summary points

- The extracellular matrix of the central nervous system contains various types of glycosaminoglycans in the form of proteoglycans.
- A fine balance between the concentrations of different proteoglycans is established in normal physiological conditions.
- Glial scar is proposed as the main inhibitor for axon regeneration following spinal cord injury.
- Glial scar is composed of various types of concentrated glycosaminoglycans in the region of spinal cord damage.
- Degradation of glycosaminoglycans at the site of spinal cord damage combined with other therapeutic strategies can help axons to recover.
- The broad substrate specificity of cABC I in accord with the composition of glial scar makes the enzyme a suitable therapeutic drug to restore tissue plasticity and axon regeneration.
- Using a high concentration of the enzyme per injection leads to molecular aggregation.
- Increasing the number of injection of the enzyme may results in immunological side effects.
- Protein engineering and drug delivery procedures are needed to produce, store, and therapeutically use of chondroitinase ABC I.
- Enzyme therapy should be used in predefined periods of time.
- Combinatorial approaches and other medical interventions along with intensive rehabilitation are being developed for locomotor recovery.

SCI	spinal cord injury

Introduction

Spasticity is one of the most common secondary complications following a complete or incomplete spinal cord injury (SCI). After SCI, the prevalence of spasticity ranges from 65% to 78%, and 35% to 49% have problematic spasticity (Holtz, Lipson, Noonan, Kwon, & Mills, 2017; Maynard, Karunas, & Waring 3rd., 1990). Currently, problematic spasticity is managed through a combination of therapeutic modalities, oral medications, botulinum toxin injections, phenol neurolysis, and surgical procedures (Table 1). Pharmaceutical options include medications delivered orally, via local injections, or through intrathecal baclofen (ITB) pumps. Botulinum toxin injections and chemical neurolysis with phenol or alcohol are the first-line treatment options for problematic focal spasticity. However, after the introduction of botulinum toxins for the treatment of spasticity, the use of phenol/alcohol chemical neurolysis for spasticity management declined over the period. Potential causes of the decline in neurolysis use include laborious techniques that required more precise skill in the pre-ultrasound era. There is a concern for the risk of loss of sensation, dysesthesias, and weakness. However, a review of existing evidence suggests that chemical neurolysis with phenol and alcohol has demonstrated effectiveness in eliminating clonus, decreasing spasticity, improving joint range of motion, decreasing painful spasms, and improving function (Akkaya et al., 2010; Gunduz, Kalyon, Dursun, Mohur, & Bilgic, 1992; Jang et al., 2004; Karri, Mas, Francisco, & Li, 2017; Karri, Zhang, & Li, 2020). In our experience, ultrasound guidance and electrical stimulation improved these procedures' efficiency and quality.

Poorly controlled severe spasticity after SCI can result in multiple complications, including the development of joint contractures (Fig. 1), inability to participate in therapy, skin breakdown, decreased function, poor sleep, and poor quality of

Diagnosis and Treatment of Spinal Cord Injury. https://doi.org/10.1016/B978-0-12-822498-4.00026-9

TABLE 1 Current treatments approach for management of spasticity in spinal cord injury[a].

Physical Modalities and Therapeutics	Passive or active stretching, Splinting, serial casting, Heat and cold application, Electrical stimulation, Vibration therapy, Orthoses, etc.
Commonly prescribed oral medications	Baclofen, Tizanidine, Diazepam, Dantrolene, Clonidine, etc.
Local interventions	Diagnostic nerve blocks: lidocaine, bupivacaine Neurolysis: phenol, alcohol Chemodenervation (botulinum toxins serotypes A and B)
Surgical interventions	Tendon lengthening procedures, Tendon transfers Intrathecal baclofen pump implantation, Dorsal rhizotomy Peripheral neurectomy

[a]*These are commonly prescribed treatments for spasticity and not an exclusive list of treatment options.*

FIG. 1 Joint contracture and deformities due to delayed spasticity management.

life (Holtz et al., 2017; Rekand, Hagen, & Gronning, 2012; Sezer, Akkus, & Ugurlu, 2015). In people with cervical SCI, we are often faced with managing problematic spasticity in all four extremities. In this scenario, a combination of treatment approaches, including phenol or alcohol neurolysis, may help manage spasticity effectively and prevent complications due to poorly controlled spasticity (Escaldi, 2018; Viel, Pellas, Ripart, Pelissier, & Eledjam, 2005). Besides, there are many other case scenarios where neurolysis can be a very useful tool to manage spasticity effectively. Such scenarios include patient refusal of ITB therapy, contraindications to ITB therapy due to ongoing infectious process, hypersensitivity to baclofen, and insufficient resources to pursue botulinum toxin injections or ITB therapy.

Additionally, botulinum toxin and intrathecal baclofen therapies are not available in many parts of the world to date. Untreated spasticity can lead to significant limitations in function and limit recovery (Tibbett, Widerstrom-Noga, Thomas, & Field-Fote, 2019; van Cooten, Snoek, Nene, de Groot, & Post, 2015). Therefore, it is essential to incorporate cost-effective alternative therapies such as phenol neurolysis to treat spasticity. This chapter will describe the following with regard to phenol neurolysis: mechanism, techniques, dosing, risks, and benefits. It will demonstrate the procedure's application in people with SCI with a case study. These procedures are similar to those for alcohol neurolysis.

Phenol or alcohol neurolysis history

The usefulness of chemical neurolysis or nerve block was first recognized in 1863 by Luton to treat pain due to phenol's and alcohol's ability to block nerve conduction (D'Souza & Hooten, 2021). There were many reports of loss of motor function after intrathecal injections of phenol for pain management in the 1950s (Kelly & Gautier-Smith, 1959; Liversedge & Maher, 1960). Between 1964 and 1967, Khalili et al. published their experience of performing peripheral nerve blocks

in patients diagnosed with a stroke, cerebral palsy, and spinal cord injury (Khalili & Betts, 1967). They reported improved spasticity in the muscles following nerve block by a 2%–3% phenol solution to mixed or motor nerves (Khalili & Betts, 1967). They also reported several unanticipated side effects, including loss of sensation in <1% instances following a nerve block. Subsequently, peripheral motor point blocks were performed to minimize sensory side effects under electromyography (EMG) and electrical stimulation guidance (Copp, Harris, & Keenan, 1970; Halpern & Meelhuysen, 1966).

Mechanism of action

Phenol, also known as carbolic acid (C_6H_5OH), is a benzene ring. In a solid state, it exists as a crystal. It is water-soluble at room temperature at ≤6.7% concentration. Phenol is typically used in 3%–6% concentration (Escaldi, 2018). When injected at a concentration of 5% and above, phenol denatures protein, which results in tissue necrosis and axonal degeneration (D'Souza & Hooten, 2021; Escaldi, 2018; Felsenthal, 1974). The effects of neurolysis last longer with 5%–6% concentration. Phenol at <3% concentration causes demyelination and some axonal destruction, resulting in shorter-lasting effects (Horn, Singh, & Dabrowski, 2015). The phenol application to the nerve trunk or motor point results in a short-term anesthetic effect that lasts for few hours. Short-term and immediate local anesthetic effects result in instant spasticity relief (D'Souza & Warner, 2021; Zhang, Darji, Francisco, & Li, 2021). However, long-term and full effects may take 7–9 days after injections due to the time required for axonal degeneration (Zhang et al., 2021). The duration of effects is dependent on the site of injection and concentration of phenol used (Halpern & Meelhuysen, 1967; Sung et al., 2001). Following injection at the proximal portion of a nerve using a higher concentration of phenol, the nerve takes 6–9 months to re-generate, whereas injections at the nerve's distal portion takes 3–4 months to recover. Repeated neurolysis can result in permanent nerve damage and muscle atrophy (Horn et al., 2015).

Phenol neurolysis technique and dose

Extensive knowledge of the anatomy of mixed, motor, and sensory nerve pathways and muscles innervated by individual motor branches is essential to prevent serious side effects and improve outcomes. Phenol neurolysis can be performed with anatomic localization, electrical stimulation guidance, or ultrasound guidance. Often, these techniques are combined to maximize the efficiency of the procedure and minimize errors in localizing targets. In some cases, first performing a temporary nerve block with 1% lidocaine prior to phenol neurolysis may help assess the efficacy and potential loss of function that can be expected with the long-lasting procedure. The injection technique and materials required for performing a motor point block and peripheral neurolysis are similar. Teflon-coated electromyography needles of 25- to 27-gauge, surface electrodes, and a portable electrical stimulator are required for performing injections with electrical stimulation guidance. Anatomical localization along with electrical stimulation allows rapid localization of motor points or peripheral nerves. The use of a lower amount of current (≤1 mA) and stronger contractions suggests closer proximity to motor points or target nerve branches. Ultrasound guidance combined with electrical stimulation can decrease side effects and improve procedure efficiency and efficacy. In a study, injections performed under combined ultrasound and electrical stimulation guidance resulted in a lower phenol dose compared to electrical stimulation guidance alone (Karri et al., 2017; Kaymak, Kara, Gurcay, Aydin, & Ozcakar, 2019; Matsumoto, Berry, Yung, Matsumoto, & Munin, 2018). Motor points typically require multiple injection sites for a reduction in spasticity. Phenol neurolysis of proximal nerve trunk requires injection at one to two sites, and electrical stimulation results in stronger muscle contraction. However, ultrasound guidance requires additional equipment and skill. Typically, at each injection site, 0.2–0.5 mL of 5%–6% phenol is injected. However, the phenol amount per nerve or site may vary based on the practitioner's expertise and guidance used for injections (Karri et al., 2017).

Immediate spasticity relief experienced due to phenol's anesthetic effect during the procedure can be used to titrate the dose when injecting motor points. There are no clear studies about the target recommended dose, but the current literature recommends no more than 1.0–1.2 g in total (e.g., 20 mL of 5%–6% concentration) (D'Souza & Warner, 2021; Gaid, 2012; Horn et al., 2015). However, a study reported safe use of up to 30 mL of 6% phenol (Karri et al., 2017). Systemic doses of 8.5 g and above can result in serious side effects, including cardiovascular and central nervous system dysfunction (Escaldi, 2018; Horn et al., 2015).

The decision to inject the proximal portion of nerve vs distal motor points depends on various factors, including time from injury, complete vs incomplete injury, spasticity management goals, and current functional status. A careful evaluation and discussion of the risks and benefits of various options for spasticity management should be discussed. Before neurolysis, evaluate for any potential for nerve transfers to improve function. It is also essential to remember that while preserving motor points is vital for potential neurorecovery, poorly controlled spasticity can prevent participation in therapies, result in joint contractures, and significantly limit recovery. Current evidence suggests a significant improvement in spasticity in the upper and lower extremity muscles following chemical neurolysis (Awad, 1972;

Chang & Boudier-Reveret, 2020; Chua & Kong, 2001; Copp et al., 1970; Easton, Ozel, & Halpern, 1979; Elovic et al., 2009; Jang et al., 2004; Karri et al., 2017, 2020; Keenan, Tomas, Stone, & Gersten, 1990; Kong & Chua, 2002; Lee, Kim, Kim, Ro, & Lee, 2020).

Upper extremity targets

A list of the phenol neurolysis of upper extremity targets in people with SCI is presented in Table 2. Our center's data suggest that medial and lateral pectoral nerve neurolysis and musculocutaneous motor point block are the most common upper extremity targets for phenol neurolysis in people with SCI. Spasticity of shoulder adductors and shoulder internal rotators muscles can be very severe and challenging in people with spinal cord injury. Stretching is often limited due to pain in the shoulder and inadequate response to botulinum toxin injections. Phenol neurolysis to medial and lateral pectoral and thoracodorsal nerves can successfully decrease spasticity in these muscle groups and improve shoulder range of motion. The pectoral nerves can be easily located with ultrasound guidance between the pectoralis major and pectoralis minor (Fig. 2). Due to the proximity of these nerves to the lungs and pleura, ultrasound guidance is recommended. The musculocutaneous nerve is a mixed nerve and supplies sensation to the lateral forearm by its terminal branch known as the lateral cutaneous nerve of the forearm. The musculocutaneous nerve can be localized near the pectoralis major tendon's distal insertion between the coracobrachialis and the short head of the biceps on the arm's medial side (Keenan et al., 1990). In people with incomplete injury, a motor point block to target muscle is recommended to prevent weakness of the elbow flexors and loss of sensation over the forearm (Sirico, Zappia, Di Meglio, Castaldo, & Nurzynska, 2020). The motor point block to distal muscle groups (finger flexors and wrist flexors) of the upper extremity or mixed nerves can be targeted with ultrasound or electrical stimulation guidance. However, we must isolate the target motor branches or perform motor point blocks to prevent unintended sensory loss and weakness in other muscle groups supplied by the target nerve (Karri et al., 2020; Sirico et al., 2020).

Lower extremity targets

A list of the phenol neurolysis of lower extremity targets in people with SCI is presented in Table 3. The obturator nerve and tibial motor points are the lower extremities' most frequent targets of phenol (Ghai et al., 2013). Though the obturator nerve is a mixed nerve, its sensory branch supplies only a small area over the knee's medial aspect. The obturator nerve can be localized 1–2 cm below and lateral to the pubic tubercle and medial to femoral vessels in the thigh's upper part. Sciatic motor branches to the hamstrings can be localized at two locations; one is located at 20% and the other at 33% of the distance from the ischial tuberosity on a line drawn from the ischial tuberosity to lateral femoral condyle (Seidel, Seidel, Gans, & Dijkers, 1996). The tibial motor points can be located 1–2 cm medial and lateral of a point located 1–2 cm below the popliteal crease's midpoint (Chua & Kong, 2001). The quadriceps are richly innervated with multiple motor points located over the muscles' mid-belly. The practitioner should be cautious while injecting motor branches of the sciatic nerve, femoral nerve, and tibial nerve as these are mixed nerves. A diagnostic lidocaine motor point can help identify cases in which people rely on their spasticity for ambulation prior to phenol motor point blocks. Accessing the motor point to

TABLE 2 Upper extremity targets for phenol neurolysis.

Spasticity pattern	Main target muscles	Nerve block or motor point block
Shoulder adduction and internal rotation	Pectoralis major, Latissimus dorsi	Medial and lateral pectoral nerves, thoracodorsal nerves
Elbow flexors	Brachialis, Biceps brachii, BCR	Musculocutaneous motor points to brachialis and biceps Radial motor branches to BCR
Elbow extensors	Triceps lateral head, long head, and medial head	Radial motor branches to triceps
Pronation	Pronator teres	Median motor points to pronator teres
Wrist flexors	FCR and FCU	Median nerve motor branches to FCR and ulnar motor branches to FCU
Finger flexors	FDS and FDP	Respective median and ulnar motor branches to FDS and FDP

FIG. 2 Lateral pectoral neurolysis under ultrasound and electrical stimulation guidance.

TABLE 3 Lower extremity targets for phenol neurolysis.

Spasticity pattern	Main target muscles	Nerve block or *Motor* point block
Hip adductors	Adductor Magnus, Adductor Longus, Adductor Brevis	Obturator nerve
Hip Flexors	Iliacus, Sartorius, Rectus femoris	Femoral motor branches to iliacus, sartorius, rectus femoris
Knee flexors	Hamstrings	Sciatic motor branches to biceps femoris, semimembranosus, semitendinosus
Knee extensors	Quadriceps	Femoral motor branches to quadriceps
Ankle plantar flexors	Gastrocnemius, soleus	Tibial motor branches to gastrocnemius and soleus

the psoas major can be challenging due to the abdominal viscera and blood vessels in the vicinity. However, there are case reports in people with stroke and SCI describing successful phenol lumbar nerve block and psoas motor point block to treat hip flexor spasticity (Awad, 1972; Koyama, Murakami, Suzuki, & Suzaki, 1992).

Adverse effects

Risks associated with any injection include infection at the site of injection, pain, bleeding, and bruising. Incomplete nerve (mixed or sensory) destruction may cause dysesthesias. A complete nerve block is required to get relief from dysesthesias. A retrospective study evaluating 293 phenol neurolysis procedures reported the following incidence of adverse events; 4% pain. 2.7% inflammation, 0.7% dysesthesias, and 0.7% hypotension (Karri et al., 2017). Other complications include swelling and loss of sensation. Swelling, pain at the injection site, hypotension, and inflammation all resolve within a few days. Accidental intravascular injection of phenol can cause systemic side effects, including flushing, nausea, vomiting, cardiovascular and central nervous system depression, resulting in cardiac arrest and coma (Lee et al., 2020). Systematic side effects are uncommon in doses less than 100 mg (D'Souza & Warner, 2021).

Case study

A 49-year-old African American male patient sustained a pedestrian motor vehicle accident, resulting in incomplete quadriplegia (C4 neurological level), pictured in Fig. 3. After his injury, he had a 2-month stay in an intensive care unit. He was discharged to a skilled nursing facility. He presented to our SCI center 8 months post-injury with several SCI-associated complications, including a stage 4 sacral pressure injury, multiple joint contractures, and severe generalized spasticity. He was bed-bound since the time of injury. After admission to our inpatient rehabilitation facility, oral medications for spasticity control were optimized with minimal benefits. Given significant spasticity in all four extremities, he needed multiple interventions to manage his spasticity to improve his function. Phenol motor point blocks to the bilateral shoulder abductors, elbow flexors, and hip adductors were performed. We also recommended intrathecal baclofen therapy. However, he needed immediate relief from his severe spasticity as it interfered with his positioning in bed and his wheelchair. It also negatively affected his hygiene surrounding the sacral pressure injury, impeding its healing. He also benefitted from botulinum toxin injections to the bilateral pronators, wrist flexors, and finger flexors. These interventions decreased spasticity and improved active and passive ROM.

Figure 3A. Baseline

Figure 3B. After hip adductors, shoulder adductor and elbow flexor motor point blocks with phenol

Figure 3C. Improved spasticity allowed the patient to sit and operate a power chair

Figure 3D. Improved spasticity allowed him to participate in a standing activity

FIG. 3 Effects of phenol neurolysis and spasticity management in a person with SCI.

Physical therapists (PT) and occupational therapists (OT) worked with this patient to manage his spasticity to gain range of motion and prevent further contractures through stretching, joint mobilization, splinting, positioning, and weight-bearing. OT and PT collaborated to create a bed positioning program to facilitate prolonged stretch of spastic muscles and relieve pressure over the sacral wound. His therapy program was updated and modified as the patient gained range of motion in joints through spasticity management efforts. The patient's mobility improved, allowing us to order a power wheelchair (PWC) to improve his access to his environment. Switch access enabled the patient to perform his weight shifts independently and communicate with his friends and family through a Bluetooth joystick connection to a tablet. During physical therapy, the patient worked on prolonged stretching in various positions, including supine, prone, and standing in a standing frame. PT also worked with the patient on safety and endurance with PWC mobility and independence with instruction of all assistance needed for functional mobility and positioning. Improvements in posture allowed for better positioning in bed, and sitting in a PWC resulted in a healed sacral pressure injury without surgical intervention. Improved function achieved was translated into being able to operate a PWC, perform independent pressure reliefs via power tilt, access a tablet with assistive devices, and feeding himself with set up. Caregiver burden for transfers and positioning decreased from 2 people to 1 person.

Conclusion/summary

Severe spasticity can be debilitating and often challenging to manage if appropriate interventions are delayed. A comprehensive team approach to spasticity management can prevent complications and improve quality of life after SCI. In complex situations, a combination of multiple treatment options is required to improve function and independence. Phenol neurolysis can be a very useful tool in these tricky situations. Currently, limited evidence and our experience suggest that chemical neurolysis is a safe, useful tool for spasticity management in people with SCI. Besides, phenol neurolysis utilization has been shown to be associated with no procedure-related severe complications and only a small incidence of observed adverse effects. Ultrasound guidance along with electrical stimulation can reduce the total required dose and minimize procedure-related side effects.

Applications to other areas of neuroscience

Phenol or alcohol neurolysis has been used to manage spasticity in various upper motor neuron disorders. Other than spinal cord injury, the most common diagnoses for which this technique is used are stroke, brain injury, and multiple sclerosis (Karri et al., 2017; Kong & Chua, 1999, 2002; Mas, DiTommaso, & Li, 2019). It is often used in concert with botulinum toxin injections, especially when multiple areas require treatment to avoid using more than the recommended amount of either medication (Karri et al., 2020). Phenol neurolysis can also be used to treat spasticity in children. It is frequently performed to treat hip adductor and elbow flexor spasticity in children with cerebral palsy. Children may not tolerate this procedure, especially if multiple nerves are injected. For these reasons, phenol neurolysis is often performed under general anesthesia in children (Gormley, Krach, & Piccini, 2001). Few case reports of successful use of phenol neurolysis manage dystonia have been reported in the literature (Garcia Ruiz & Sanchez Bernardos, 2000; Kim, Lee, Ko, Ko, & Chung, 2003; Takeuchi, Chuma, & Mano, 2004). Phenol neurolysis has been used for decades in the management of persistent and intractable pain in various conditions. Phenol neurolysis or nerve blocks are frequently used to manage pain in cancer and other diagnoses resulting in chronic pain (Filippiadis et al., 2019; Koyyalagunta & Burton, 2010). It has been reportedly used to manage severe chronic nonmalignant pain to target pain generators, including the lumbar sympathetic chain, medial branches to the facet joints of the spine, the sacroiliac joint, the intercostal nerves, the occipital nerves, and the paracoccygeal area (Welksler et al., 2007).

Mini-dictionary of terms

Neurolysis: Targeted mechanical or chemical injury to the nerve.

Dysesthesia: Abnormal, painful sensation due to damage to the peripheral or central nervous system.

Motor point: Location where motor branches of the nerve enter the muscle.

Nerve block: Injection of a chemical agent to cause temporarily or permanently block the nerve conduction to treat pain, spasticity, etc.

Demyelination: Damage to the myelin sheath, a protective outer layer of the nerve, which helps in nerve conduction.

Spasticity: Muscle tightness or spasms due to upper motor neuron injury such as spinal cord injury, stroke.

Motor nerve: Peripheral nerve fibers that transmit signals from the brain and spinal cord to the muscles.

Sensory nerve: Peripheral nerve fibers that carry sensory information to the spinal cord and brain.
Mixed nerve: A peripheral nerve that carries both sensory and motor fibers.
Intrathecal baclofen pump: A system that delivers baclofen into intrathecal space.

Key facts of phenol

- Phenol is a chemical, also known as carbolic acid (C_6H_5OH), a benzene ring.
- At room temperature, phenol dissolves in water.
- Phenol is used at low concentrations in household cleaners as a disinfectant and antiseptic.
- Phenol is also used as a spray in a concentration of 1.4% for pain relief from sore throat.
- The usefulness of chemical neurolysis or nerve block was first recognized in 1863 for treating pain.
- Accidental exposure of large quantities of phenol can be lethal to humans.

Summary points

- Poorly controlled severe spasticity after spinal cord injury can result in multiple complications, including the development of joint contractures, inability to participate in therapy, skin breakdown, decreased function, poor sleep, and poor quality of life.
- Phenol neurolysis is a cost-effective tool to manage spasticity, which requires skill to localize to the target nerve or motor points.
- Phenol neurolysis can be performed with anatomic localization, electrical stimulation guidance, or ultrasound guidance. Often these techniques are combined to maximize the efficiency of the procedure and minimize errors in localizing targets.
- 5%–6% phenol is typically used for spasticity management with effects lasting from 3 to 9 months.
- Medial pectoral nerves, lateral pectoral nerves, and musculocutaneous motor branches are common targets of the upper extremity for treating shoulder adductor and elbow flexor spasticity.
- Obturator nerve and tibial motor nerves are frequently injected targets of the lower extremity to address hip adductor and ankle plantar flexor spasticity.
- Local adverse effects include pain, dysesthesias, loss of sensation, and swelling.
- Systemic severe side effects can result from the intravascular injection of phenol, resulting in cardiac arrest and coma.

Abbreviations

BBB	blood brain barrier
BMP	bone morphogenetic protein
CNS	central nervous system
CST	corticospinal tract
DCC	deleted in colorectal cancer
GPI	glycosylphosphatidylinositol
MCAO	middle cerebral artery occlusion
MPTP	1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine
MS	multiple sclerosis
NMO	neuromyelitis optica
PD	Parkinson's disease
RGC	retinal ganglion cell
RGM	repulsive guidance molecule
Rho GEF	Rho guanine nucleotide exchange factor
SCI	spinal cord injury
SN	substantia nigra
TBI	traumatic brain injury
UEMS	upper extremity motor score

Introduction

The repulsive guidance molecule (RGM) is a membrane-associated glycosylphosphatidylinositol (GPI)-anchored glycoprotein, which was identified as an axon guidance molecule in the retinotectal system (Monnier et al., 2002). By analyzing the development of the retinotectal projection system in chicks—a method frequently used to study the molecular basis of topographic projections, including axon guidance cues—Monnier et al. found that RGM is expressed in a spatial gradient manner along the anterior–posterior axis in the tectum (Fig. 1A). Importantly, in growth cone collapse assays, temporal, but not nasal, retinal growth cones collapsed when confronted with RGM-decorated membranes (Fig. 1B). Similarly, in the stripe assay (Walter, Kern-Veits, Huf, Stolze, & Bonhoeffer, 1987), RGM guides axonal elongation only for temporal retinal axons (Fig. 1C). These findings strongly suggest that RGM can act as an axon-specific repulsive guidance molecule (Monnier et al., 2002).

However, the receptor mechanism for RGM function was not defined at that time. In 2004, Rajagopalan et al. and Matsunaga et al. reported that neogenin mediates the biological effects of RGM as its cognate receptor (Matsunaga et al., 2004; Rajagopalan et al., 2004). Strikingly, neogenin was revealed to be expressed in a temporal–nasal gradient in the retina (Rajagopalan et al., 2004); thus, the repulsiveness of temporal, not nasal, retinal axons by RGM is well explained by RGM–neogenin interactions (Fig. 1A). RGM is also found to act as a co-receptor for bone morphogenetic proteins (BMPs) and modulates BMP signaling (Babitt et al., 2005).

Since then, RGM signaling in the central nervous system (CNS) has been extensively studied and a wide range of functions has been reported; RGM plays multiple roles in neuronal development [e.g., neural tube closure (Matsunaga

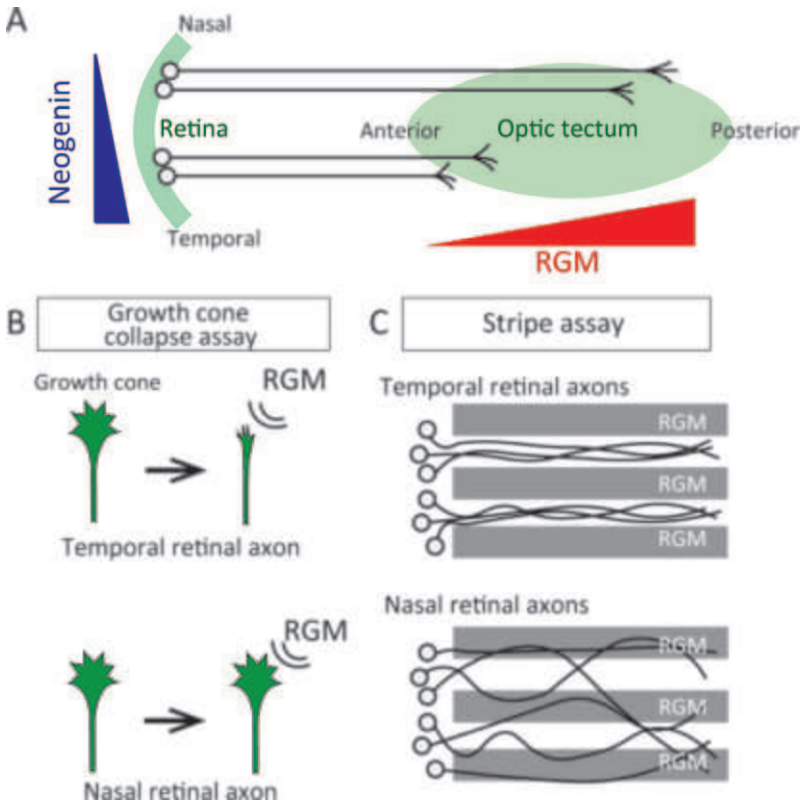

FIG. 1 RGM is an inhibitory axon guidance molecule. (A) Schematic illustration of retinotectal projections and expression patterns of RGMa and neogenin. Nasal retinal ganglion cell (RGC) axons project to the posterior part of the optic tectum, whereas temporal RGC axons project to the anterior part of the tectum. RGM is expressed in an increasing anterior–posterior gradient manner in the tectum, and neogenin is expressed along an elevating nasal–temporal gradient in the retina. (B) Representation of growth cone collapse assay. RGM exerts growth cone collapse effects only for temporal retinal axons. (C) Representation of stripe assay. The gray colored stripe indicates membrane fractions from RGM-transfected cells, whereas the white colored stripe represents membrane fractions from mock-transfected cells.

et al., 2004)], and is also involved in the pathophysiology of various CNS diseases, as discussed below. Moreover, external to the CNS, RGM has been shown to regulate endochondral bone formation (Zhou et al., 2010), iron homeostasis (Babitt et al., 2006), and inflammation (Körner et al., 2019). In mammals, at least three homologues of RGM, RGMa, RGMb (also known as DRAGON), and RGMc (also known as hemojuvelin, HFE2), have been identified. Among them, RGMa is most closely related to chicken RGM (80% homology), and most of the critical findings in CNS development/disease are obtained from RGMa research. Thus, in this review, we mainly focus on the functions of RGMa.

Characteristics of RGMa

Ligand–receptor interactions and downstream signaling of RGMa

As mentioned above, RGM binds to neogenin, a transmembrane protein originally isolated from chick cerebellum as a homolog of deleted in colorectal cancer (DCC: a receptor for the axon guidance molecule netrin-1). RGM also binds to BMP morphogens as a co-receptor and modulates BMP signaling. On the other hand, neogenin is also known as a netrin-1 receptor. How these proteins interact with each other and how downstream signaling is regulated are not fully understood. However, recent studies, including crystal structure analysis (Bell et al., 2013; Healey et al., 2015; Malinauskas, Peer, Bishop, Mueller, & Siebold, 2020), provide direct insight into their interactions.

The major binding site of RGM for neogenin is the carboxyl-terminal domain of RGM (C-RGM) (Bell et al., 2013; Itokazu, Fujita, Takahashi, & Yamashita, 2012). Interestingly, two C-RGMs act as a molecular staple bringing two neogenin receptors together, and this unique architecture is proposed to be important for the subsequent activation of downstream signaling (Bell et al., 2013; Siebold, Yamashita, Monnier, Mueller, & Pasterkamp, 2017). On the other hand, the amino-terminal domain of RGM (N-RGM) has been shown to interact with BMP, and this binding is suggested to link BMP and neogenin signaling by comprising a BMP–RGM–neogenin complex (Healey et al., 2015). RGM–BMP interactions

have been thought to potentiate BMP signaling via the canonical SMAD pathway. However, a recent report revealed that RGM can compete with growth differentiation factor 5 (GDF5), a member of the BMP family, and thus act as an inhibitor of BMP signaling (Malinauskas et al., 2020). Therefore, how intracellular signaling is regulated through interactions involving N-RGM and BMPs is presumed to be context-dependent. Further studies are warranted to determine the physiological roles of RGM–BMP interactions in each developmental/pathological condition.

RGM is thought to transduce signals in both *cis* and *trans* manner. Its distinctive functions, such as inducing growth cone collapse or axon repulsion, are induced in *trans*, that is via cell-to-cell interactions. As the RGM extracellular domain is thought to be cleaved at, and secreted from, cell membranes, *trans*-signaling can be achieved by a gradient of soluble RGM (Fig. 2). However, it is unknown whether long-range signal transduction is possible.

Although a detailed picture of RGM signaling has not yet been obtained, several key aspects have been uncovered. One of the most important downstream signaling pathways involves RhoA activation by RGM, because it is widely accepted that Rho-GTPases play key roles in axon guidance and neurite growth. Indeed, the inhibition of Rho kinase, a downstream effector of RhoA, abolishes the inhibitory effects of RGMa on neurite outgrowth (Hata et al., 2006). These authors also revealed that Unc5B, a member of the netrin receptor family, interacts with neogenin as a co-receptor for RGMa and activates RhoA through LARG, a member of the Rho guanine nucleotide exchange factor (RhoGEF) subfamily (Hata, Kaibuchi, Inagaki, & Yamashita, 2009). In addition, the involvement of Ras activity was also evaluated because of its well-known functions as a mediator of growth cone collapse and neurite retraction (Elowe, Holland, Kulkarni, & Pawson, 2001). As expected, RGMa–neogenin binding has been revealed to inactivate Ras activity, leading to growth cone collapse (Endo & Yamashita, 2009).

More recently, detailed investigations unveiled more complex mechanisms surrounding RGM–neogenin signaling regulation, including the proteolytic processing of RGMa (Tassew, Charish, Seidah, & Monnier, 2012, well summarized in Siebold et al., 2017), ectodomain shedding of neogenin (van Erp et al., 2015), and ϒ-secretase cleavage of the neogenin intracellular domain (Banerjee et al., 2016). Further research is needed to elucidate how these multiple signaling pathways are regulated and integrated in vivo.

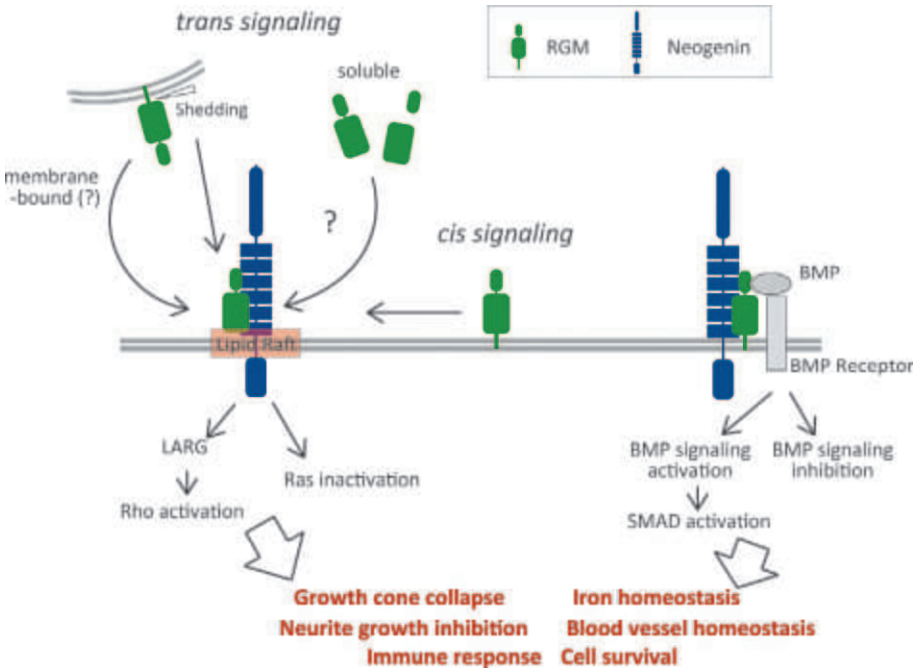

FIG. 2 RGM–neogenin interactions and downstream signaling. Schematic illustration of possible ligand-receptor interactions involving RGMa. The inhibitory effect for neurite outgrowth is brought about by *trans*-signaling; that is, neurogenin-expressing axons are repelled by cell-bound RGMa or via an RGMa gradient established by extracellular shedding. Neogenin localization to lipid rafts—membrane domains enriched in cholesterol, sphingolipids, and protein receptors, present a platform for cellular signaling events, including ligand:receptor interactions—has been proposed to be indispensable for signal transduction.

RGMa in spinal cord injury (SCI)

RGMa expression after SCI

Given that RGMa, as an inhibitory protein, is involved in neural circuit formation during development by modulating the pathfinding activity of growing axons, it is possible that RGMa exerts negative effects on axonal regeneration. To test this concept in vivo, RGMa expression in the spinal cord of adult animals under normal and SCI conditions has been addressed.

Immunohistochemical analysis of rat spinal cord using anti-C-RGMa antibody revealed its localization to neurons and oligodendrocytes under normal conditions (Hata et al., 2006; Schwab, Conrad, et al., 2005). After SCI, RGMa expression around the lesion site is upregulated; with expression by neurons, oligodendrocytes, certain reactive astrocytes, activated microglia, and infiltrating leukocytes (Hata et al., 2006; Schwab, Conrad, et al., 2005). These observations support the possibility that RGMa is an inhibitory protein against axonal regeneration after SCI; therefore, RGMa neutralization is considered to be a potential therapeutic strategy to attenuate neural deficits induced by SCI. An increase in RGMa around the SCI lesion site is also observed in primates (Nakagawa et al., 2019). In that study, RGMa was reported to be mainly expressed by Iba-1-positive microglia/macrophages.

Importantly, RGMa expression patterns in the human spinal cord have also been reported. In the uninjured spinal cord, RGMa is expressed at low levels by neurons and glial cells. However, immunoreactivity for RGMa in the spinal cord is significantly increased following SCI, and the localization of RGMa in neurons, axons, and glial cells has been confirmed (Mothe et al., 2017). On the other hand, the RGMa receptor neogenin is expressed by neurons in the spinal cord in both rats and humans (Mothe et al., 2017).

Taken together, RGMa upregulation induced by SCI is common across divergent species, suggesting the significance of RGMa in the pathophysiology of CNS injury.

RGMa inhibition promotes recovery after SCI in rodents

The first direct evidence of the therapeutic effects of RGMa inhibition on SCI was reported in 2006 (Hata et al., 2006). To test the hypothesis that upregulated RGMa plays a negative role in axonal regeneration in vivo, Hata et al. generated an RGMa-neutralizing antibody (directed against RGM residues 309–322). After receiving Th9/10 dorsal transection, which resulted in both dorsal (main) and lateral corticospinal tract (CST) injury, rats were treated with the RGMa-neutralizing antibody via an osmotic mini-pump with catheters placed near the lesion site, and locomotor functions were monitored. As expected, the Basso–Beattie–Bresnahan (BBB) locomotion score (Basso, Beattie, & Bresnahan, 1995) was significantly improved by RGMa inhibition. The authors also performed anatomical tracing studies and observed a lesser degree of CST retraction, a greater number of collateral formations, and a significant amount of axon extension through the lesion site (Fig. 3A). This enhanced anatomical regeneration temporally correlated with functional recovery.

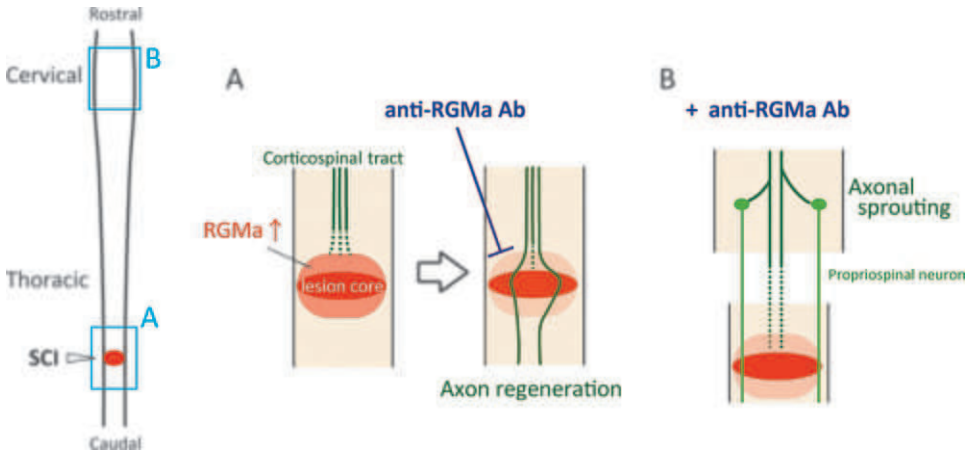

FIG. 3 RGMa neutralization enhances axonal regeneration and neural circuit reorganization after spinal cord injury in rodents. RGMa neutralization promotes several types of neuroplasticity after spinal cord injury. (A) RGMa is upregulated around the lesion site and limits axonal regeneration. Anti-RGMa treatment results in axonal growth of the corticospinal tract (CST). (B) Anti-RGMa treatment is suggested to enhance neural synaptic rearrangement in the cervical spinal cord, distant from the lesion site. Collaterals from hind-limb axons possibly make connections to descending long propriospinal neurons to compensate for the damaged circuit (Bareyre et al., 2004).

Using the same experimental setting, Kyoto et al. tested the possibility that neural circuit plasticity might be enhanced by anti-RGMa antibody treatment—even in lesions distant from the injury site (Kyoto et al., 2007). The results showed that antibody treatment facilitated synapse formation at the level of the cervical spinal cord (Fig. 3B), which may contribute to the rerouting of hind-limb CST connections through propriospinal neurons (Bareyre et al., 2004; Fink & Cafferty, 2016; Oudega & Perez, 2012). This observation may be explained by the notion that the adult CNS offers an inhibitory environment for adoptive reorganization (i.e., neural circuit remodeling) and RGMa is one of its major components; therefore, RGMa inhibition can contribute to the establishment of reorganization-permissive environments.

On the other hand, Tassew et al. explored strategies to inhibit neogenin (Tassew et al., 2014). During developmental stages, neogenin is known to act as a dependence receptor that induces cell death in the absence of RGM (Matsunaga et al., 2004). Therefore, targeting neogenin instead of RGMa may be beneficial, not only for neural circuit reorganization, but also for neuronal survival after SCI. Based on the observation that the receptor functions of neogenin require its localization in lipid rafts, the authors addressed whether blocking neogenin raft association improves SCI outcomes. They found that interactions involving the neogenin 4Ig domain and the N-terminal regions of RGMa (N-RGMa) are critical for the attraction of neogenin to lipid rafts, and recombinant 4Ig treatment effectively abolishes their interactions. Thus, they treated SCI rats with 4Ig (intravenous injection or local intrathecal infusion). As expected, axonal regeneration and functional recovery (as assessed by BBB scores and ladder walk tests) were significantly enhanced. Furthermore, this treatment attenuated neuronal loss in perilesional neurons.

Based on this evidence, humanized monoclonal antibodies specific for N-RGMa were generated (Demicheva et al., 2015), and their therapeutic potential in impact-compression SCI was tested (Mothe et al., 2017). To provide a clinically applicable strategy, the authors examined the efficacy of RGMa inhibition by systemic administration of humanized anti-RGMa antibody and revealed that this treatment effectively enhanced functional recovery (as assessed by BBB scores, ladder walk tests, and footprint analysis). Moreover, by histological and anatomical analysis, it was also confirmed that anti-RGMa antibody treatment enhances neuronal survival and axonal regeneration. Interestingly, anti-RGMa antibody treatment also attenuated neuropathic pain after SCI. Although effects on microglia/macrophage were suggested, the precise mechanisms involved remain unknown. In a recent paper, Mothe et al. also reported that delayed administration (~3 h after SCI) of anti-N-RGMa antibody could still effectively enhance recovery of motor functions, with increased neuronal sparing and axonal plasticity (Mothe et al., 2020). Interestingly, the recovery of bladder function was also enhanced, indicating that anti-RGMa treatment exerts broad beneficial effects in terms of SCI convalescence.

Taken together, the effectiveness of the strategy for RGMa/neogenin signaling inhibition has been repeatedly confirmed in rodent SCI models (Table 1). In the next chapter, evidence from primates is discussed.

TABLE 1 Summary of pre-clinical studies.

Author (Year)	Species	Method of SCI	Intervention	Route of Administration	Functional Outcome	Suggested Mechanism
Hata et al. (2006)	Rat	Dorsal hemisection	anti RGMa-C antibody	intrathecal administration via osmotic minipump	Locomotor recovery ↑ (BBB score)	CST regeneration/sprouting ↑
Kyoto et al. (2007)	Rat	Dorsal hemisection	anti RGMa-C antibody	intrathecal administration via osmotic minipump	*not tested*	Synapse formation of CST in the cervical SC ↑
Tassew et al. (2014)	Rat	Impact compression	4Ig peptide (prevent RGMa-Neogenin interaction)	Intraspinal injection and continuous intrathecal derivery	Motor function ↑ (BBB score, Motor subscore, Ladder walk test)	Axonal regeneration ↑ Neuronal loss ↓
Mothe et al. (2017)	Rat	Impact compression	anti-RGMa-N human antibody	Intravenous administration	Locomotor recovery ↑ (BBB score, Motor subscore, gait analysis) Neuropathic pain ↓	Perilesional neuronal survival ↑ CST axonal growth ↑ Neuronal survival ↑
Chen et al. (2019)	Lamprey	Transection	Neogenin antisense morpholino oligo	Retrograde transport from lesion site	Restoration of locomotor activity	Survival of reticulospinal neurons ↑
Mothe et al. (2020)	Rat	Impact compression	elezanumab (human monoclonal RGMa antibody)	Intravenous delayed administration	3h post-SCI administration: Locomotor recovery ↑ (BBB score, Motor subscore) Bladder function ↑	CST axonal plasticity ↑ Serotonergic axonal plasticity ↑ Perilesional neuronal sparing ↑
Yang et al. (2020)	Rat	Compression	sh-RGMa (lentiviral vector)	Direct injection to the spinal cord	Locomotor recovery ↑ (BBB score)	Nerve regeneration ↑
Nakagawa et al. (2019)	Macaque monkey	Unilateral lesion at C6/C7	anti-human RGMa-C antibody	intrathecal administration via osmotic minipump	Manual dexterity ↑	Axonal sprouting of CST fiber ↑ CST fiber - motoneuron connection ↑

Inhibition of RGMa/neogenin signaling promotes functional recovery after SCI (Chen & Shifman, 2019; Kyoto, Hata, & Yamashita, 2007; Mothe et al., 2017, 2020; Nakagawa, Ninomiya, Yamashita, & Takada, 2019; Tassew et al., 2014; Yang & Sun, 2020).

RGMa inhibition promotes recovery after SCI in primates

Considering the clinical application of potential therapies to SCI patients, differences in possible mechanisms underlying neural circuit remodeling between higher primates and rodents should be taken into account. For example, the CST in rodents mainly descends to the dorsal funiculus, whereas in primates, the CST passes through the lateral and ventral portions of the spinal cord. More importantly, direct corticomotoneuronal connections, which are thought to be critically involved in manual dexterity in primates, are lacking in rodents (Lemon, 1993). Restoring hand dexterity remains a key clinical challenge and addressing whether potential treatments have beneficial effects in terms of skilled motor behavior in primates is of enormous importance.

Therefore, to test the effects of anti-RGMa antibody treatment in higher primates, Nakagawa et al. conducted SCI experiments in rhesus monkeys (Nakagawa et al., 2019). Unilateral spinal cord lesions were performed by transection at C6/C7 (Fig. 4A), which led to the complete loss of lateral CST fibers below the lesion. Then, a neutralizing antibody against C-RGMa was continuously delivered to the lesion site via an osmotic pump. Manual dexterity was assessed by a reaching/grasping task (Nakagawa, Ninomiya, Yamashita, & Takada, 2015) and the modified Brinkman Board Test (Freund et al., 2009). In both tests, monkeys were required to grasp food pellets placed in small horizontal or vertical slots (Fig. 4B). The results of these tests conformed a drastic improvement in the motor performance of the animals in the anti-RGMa antibody-treated group.

Further, the anatomical basis for this improvement was investigated. As summarized in Fig. 4C, anti-RGMa antibody treatment enhanced axonal sprouting of CST fibers arising from the motor cortex in the spinal cord at C7-Th1. Moreover, numbers of biotinylated dextran amine (BDA)-labeled direct contacts of CST fibers with wheat germ agglutinin (WGA)-labeled motor neurons (i.e., corticomotoneuronal direct connections) at the levels of C7, C8, and Th1 were significantly increased. These findings suggest that sprouting CST fibers can find appropriate target motoneurons to promote the efficient recovery of motor functions. Furthermore, inactivation of the contralesional motor cortex by muscimol injection in the anti-RGMa antibody-treated animals was performed. The otherwise recovered manual dexterity was then completely abolished.

Taken together, it is reasonable to assume that improved functional recovery of manual dexterity can be achieved by enhancement of axonal reorganization induced by anti-RGMa antibody treatment.

Clinical studies

Based on preclinical findings, two clinical trials using anti-RGMa antibody are, as at October 2020, underway. One of these, MT-3921, involves a monoclonal antibody against the C fragment of RGMa and is under investigation for the

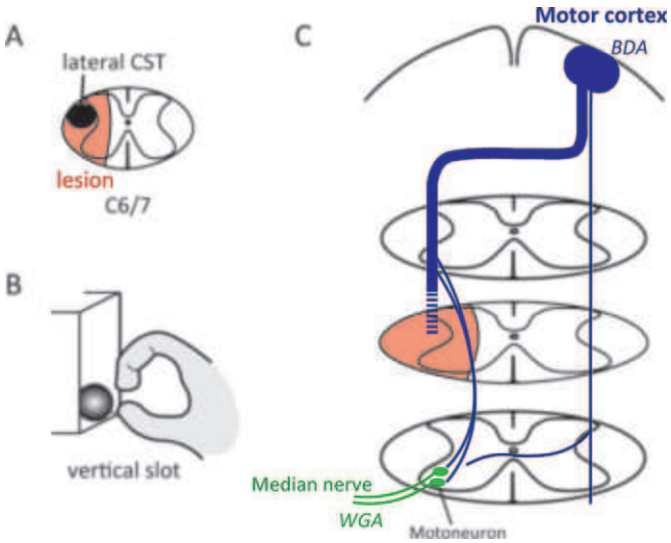

FIG. 4 RGMa neutralization enhances neural circuit reorganization after SCI in primates. (A) Schematic representation of spinal cord lesions in a study by Nakagawa et al. (2019). (B) Behavioral analysis of manual dexterity. Motor performance was greatly recovered by anti-RGMa antibody treatment. This treatment also advanced the commencement of recovery following SCI. (C) RGMa neutralization enhances axonal sprouting of corticospinal tract (CST) fibers. CST axons are labeled by anterograde injection of anterograde tracer (BDA; biotinylated dextran amine). For motoneuron labeling through median nerves, wheat germ agglutinin (WGA) was directly injected into the median nerve.

treatment of acute SCI (NCT04096950, www.clinicaltrials.gov, sponsored by Mitsubishi Tanabe Pharma Development America, Inc.). Another is elezanumab (ABT-555), a monoclonal antibody against the N fragment of RGMa. This antibody is also planned for patients with acute traumatic SCI with C4, C5, C6, or C7 (neurological level) injury (NCT04295538, www.clinicaltrials.gov, sponsored by AbbVie). These trials will determine whether the beneficial effects of RGMa neutralization are also observed in patients suffering from CNS injury.

RGMa in other CNS disorders

Increasing evidence suggests that RGMa is also involved in various CNS disorders, including multiple sclerosis (MS), stroke, traumatic brain injury (TBI), neuromyelitis optica (NMO), and Parkinson's disease (PD). Especially in MS, RGMa inhibition is considered one of the most promising therapeutic strategies (Demicheva et al., 2015; Muramatsu et al., 2011; Tanabe, Fujita, Ikuma, & Yamashita, 2018; Tanabe & Yamashita, 2014). Using an experimental autoimmune encephalomyelitis (EAE) model, Muramatsu et al. showed that anti-RGMa antibody treatment attenuates the symptoms of EAE mice by modulating T cell responses. Particularly impressive is the effect of anti-RGMa treatment on peripheral blood mononuclear cells (PBMCs) obtained from MS patients; this treatment leads to a reduction in their proliferative responses and pro-inflammatory cytokine production (Muramatsu et al., 2011). In another study, RGMa was found to be highly expressed by Th17 cells and mediated neurodegeneration through direct interaction with its receptor, neogenin, which is expressed by neurons (Tanabe & Yamashita, 2014). Demicheva et al. performed histological analysis of human autopsied MS brain tissue and revealed that RGMa is expressed in MS lesions and by infiltrating lymphocytes. To test neural regeneration capacity, they employed a rat targeted-EAE model (established by Kerschensteiner et al., 2004) involving the spinal cord and optic nerve and demonstrated that anti-RGMa treatment promotes both functional recovery and regenerative axonal growth, accompanied by enhanced remyelination and decreased activation of microglia/macrophages (Demicheva et al., 2015). Taken together, anti-RGMa antibody is expected to attenuate MS symptoms by modulating immune responses and axonal regeneration.

The effects of anti-RGMa antibody treatment in NMO were also reported. Harada et al. established a localized NMO model by injecting NMO-IgG obtained from AQP4-Ab–positive NMO patients, into the thoracic spinal cord of rats. After NMO-IgG injection, animals developed motor dysfunction in the tail and hind-limbs, accompanied by the loss of astrocytes in lesion areas, and systemic injection of anti-RGMa antibody effectively attenuated motor deficit, microglial activation, and IL-17A+ T-cell infiltration (Harada et al., 2018).

Several lines of evidence also indicate that RGMa/neogenin pathway inhibition is also a promising strategy to treat patients with cerebral infarction. Based on the observation that RGMa is upregulated in the infarct and peri-infarct (penumbral) lesions of the brain in patients suffering from cerebral infarction (Schwab, Monnier, et al., 2005), Shabanzadeh et al. tested the effect of anti-RGMa antibody in a middle cerebral artery occlusion (MCAO) model in rats and confirmed that such treatment effectively attenuated the infarct area and improved the functional outcomes (Shabanzadeh et al., 2015). RGMa is also suggested to be involved in the blood–brain barrier (BBB) dysfunction (Li et al., 2018), angiogenesis (Wang et al., 2018), and glial scar formation (Zhang et al., 2018) after stroke (MCAO). Recently, Yao et al. revealed that astrocytic neogenin is involved in blood vessel homeostasis. Astrocyte-specific neogenin depletion leads to an increase in the number of blood vessels with leaky BBB in the mouse cortex. Moreover, they showed that neogenin knock-out impairs BMP2-induced netrin-1 expression in astrocytes, which causes a dysregulation of blood vessel homeostasis and function (Yao et al., 2020). Though RGMa involvement was not tested in this study, RGMa may play a direct role in BBB maintenance.

RGMa is also suggested to be involved in PD. Based on the observation that RGMa is upregulated in the substantia nigra (SN) of human PD brains (Bossers et al., 2009), Korecka et al. addressed whether RGMa affects the dopaminergic system, and revealed that AAV-mediated overexpression of RGMa in murine SN results in selective degeneration of dopaminergic neurons with strong microglial activation (Korecka et al., 2017). These results indicate that upregulated RGMa in the SN of PD patients negatively affects midbrain dopaminergic neurons, possibly by inducing microglial accumulation and activation. Indeed, by using 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) mouse model, Oda et al. showed that the loss of dopaminergic neurons and accumulation of microglia/macrophages in the SN were attenuated by anti-RGMa antibody treatment (Oda et al., 2021).

In summary, RGMa has been shown to regulate a wide range of pathological events, including immune responses, neuronal survival, and BBB maintenance, following CNS damage. Because SCI also shares these pathological conditions, anti-RGMa antibody treatment might exert its therapeutic effects by modulating various pathological processes involved in SCI (Table 2).

TABLE 2 Therapeutic potential of RGMa inhibition in other CNS disorders.

	Author (Year)	Animal model	RGMa inhibition	Outcome / Suggested Mechanism

Conclusions

Over the past decade, experimental studies have greatly enhanced our understanding of neural circuit reorganization after SCI, and various neuro-restorative therapies have been proposed. In particular, a great deal of effort has been invested to identify a biological agent that can modulate the inhibitory function in axonal regeneration/reorganization, with anti-RGMa-neutralizing antibody proving to be one of the most promising candidates with great success in pre-clinical studies. Indeed, various forms of neuroplasticity, including axonal regeneration and neural circuit reorganization, have been shown to be promoted by RGMa inhibition. Moreover, anti-RGMa antibody appears to exert multiple mechanisms of action in SCI, in addition to axonal regeneration, improving neuronal viability, modulating inflammatory responses, or regulating BBB dysfunction. Hopefully, successful clinical trials of this unique therapeutic antibody will open a new window for SCI therapeutics.

Applications to other areas of neuroscience

RGMa has been shown to regulate a wide range of pathological events, including axonal plasticity, immune responses, neuronal survival, and the blood–brain barrier (BBB) maintenance, following central nervous system (CNS) damage. Because most neurological disorders share these pathological conditions to some extent, anti-RGMa antibody treatment might be beneficial for many kinds of CNS diseases.

Indeed, in preclinical studies, RGMa is suggested to be critically involved in multiple sclerosis (MS), stroke, traumatic brain injury (TBI), neuromyelitis optica (NMO), and Parkinson's disease.

In particular, in MS, RGMa inhibition is considered one of the most promising therapeutic strategies. In experimental autoimmune encephalomyelitis (EAE) model mice, anti-RGMa antibody treatment attenuates neurological symptoms by modulating T cell responses. RGMa has also been suggested to be involved in Th17-cell–induced neurodegeneration in EAE.

Inhibition of the RGMa/neogenin pathway has also been proposed as a promising strategy to treat patients with cerebral infarction. RGMa is upregulated in the infarct and peri-infarct lesions, and anti-RGMa antibody treatment improves the functional outcomes in middle cerebral artery occlusion (MCAO) model rats. In the MCAO model, involvement of RGMa in BBB dysfunction, angiogenesis, and glial scar formation has been suggested.

In the main text, we discussed the applications of anti-RGMa treatment for other neurological disorders in greater detail.

Mini-dictionary of terms

Retinotectal projection: This projection is organized in a retinotopic manner, and is frequently used to study the molecular mechanisms underlying neural circuit formation based on chemoaffinity theory.

RhoA: A member of the Rho family of GTPases. Rho proteins play a critical role in actin cytoskeletal reorganization and are thus important for cell motility. Rho activity is tightly regulated by local guanine nucleotide exchange factors (GEFs).

Dorsal transection: One of the major SCI models in rodents. The main CST of rodents descends the dorsal funiculus; thus, severe injury to this area leads to complete loss of the main CST on both sides.

Targeted EAE: As the conventional EAE model shows disseminated inflammatory lesions, testing the relationship between functional deficits and structural damage is difficult. To overcome this limitation, a localized EAE model was generated.

BMP: BMPs are a group of morphogens that belong to the transforming growth factor-β (TGF-β) superfamily, and have diverse functions in the processes of embryogenesis, development, and adult tissue homeostasis.

Key facts of axonal sprouting

CST axons have the capacity to spontaneously sprout after SCI.

Axonal sprouting is one of the mechanisms involved in neural circuit reorganization.

Axonal sprouting occurs both rostrally and caudally to the lesion and occurs from both injured and intact CST axons.

Instead of long-range regeneration, CST axons sprout over short distances and establish synaptic connections with descending propriospinal neurons.

Such newly formed connections can serve as bypass circuits and contribute to functional recovery.

Rehabilitative training or neutralization of neurite outgrowth inhibitory proteins such as Nogo-A and RGMa are thought to enhance axonal sprouting.

Summary points

- RGM was identified as an axon guidance molecule of the retinotectal system.
- RGM induces growth cone collapse and neurite growth inhibition.
- RGM exerts its neurite growth inhibitory effect by interacting with its receptor, neogenin.
- RGMa is upregulated in the injured spinal cord after SCI in rodents, monkeys, and humans.
- In rodents, anti-RGMa-neutralizing antibody treatment enhances axonal regeneration/reorganization and functional recovery after SCI.
- In monkeys, RGMa-neutralizing antibody treatment enhances neural circuit reorganization and functional recovery of hand dexterity.
- RGMa is also involved in the regulation of the immune system, gliosis, blood–brain barrier integrity, and angiogenesis.
- Two lines of clinical trials using antibodies against RGMa are currently underway.

Abbreviations

5-HTR	5-hydroxytryptamine receptor
7,8-DHF	dihydroxyflavone
Ac	acetyl group
AICAR	5-aminoimidazole-4-carboxamide ribonucleotide
Akt	protein kinase B
AMPK	adenosine monophosphate-activated kinase
AP-1	activating protein 1
ATP	adenosine triphosphate
BSCB	blood–spinal cord barrier
cGMP	cyclic guanosine monophosphate
CNS	central nervous system
CO	carbon monoxide
cyt *c*	cytochrome *c*
DEX	dexmedetomidine
DRP1	dynamin-related protein 1
EAAT	excitatory amino acid transporter
eNOS	endothelial nitric oxide synthase
ETC	electron transport chain
FDA	Food and Drug Administration
FIS1	fission 1
Glu-R	glutamate receptor
GPCR	G protein-coupled receptor
HO-1	heme oxygenase 1
IL-6	interleukin 6
MAPK	mitogen-activated protein kinase
MB	mitochondrial biogenesis
Mdivi-1	mitochondrial division inhibitor 1
Mfn	mitofusin
Mn	manganese
mPTP	mitochondrial permeability transition pore
mtDNA	mitochondrial DNA
Nrf	nuclear respiratory factor
NSC	neuronal stem cell
OPA1	optic atrophy 1
OXPHOS	oxidative phosphorylation
P	phosphate group
PDE	phosphodiesterase

Diagnosis and Treatment of Spinal Cord Injury. https://doi.org/10.1016/B978-0-12-822498-4.00028-2

PGC-1α	peroxisome proliferator-activated receptor-gamma coactivator 1 alpha
PI3K	phosphoinositide-3 kinase
PINK1	PTEN-induced kinase 1
PPAR	peroxisome proliferator-activated receptor
ROS	reactive oxygen species
SCI	spinal cord injury
SIRT1	sirtuin-1
TFAM	mitochondrial transcription factor A
TMP	tetramethylpyrazine
TNFα	tumor necrosis factor alpha
TZDs	thiazolidinediones
U	ubiquitin group
β-AR	β-adrenergic receptor

Introduction

Neuronal integrity is dependent on mitochondrial homeostasis and function, resulting in the central nervous system (CNS) being particularly sensitive to mitochondrial dysfunction (Golpich et al., 2017). Spinal cord injury (SCI) results in an intricate pathology involving heterogeneous cell types with unique roles in injury and recovery. Following SCI, mitochondria are dysfunctional, resulting in an array of consequences including decreased mitochondrial respiration and adenosine triphosphate (ATP) production, depolarization of the mitochondrial membrane, mitochondrial DNA (mtDNA) fragmentation, oxidative stress, compromised calcium homeostasis, altered mitochondrial dynamics, and cell death (Simmons, Scholpa, & Schnellmann, 2020). These cellular dysfunctions contribute to the secondary injury cascade of SCI, exacerbating injury, and hindering recovery.

Mitochondrial biogenesis (MB) is an intricate process involving the generation of new, functional mitochondria (Whitaker, Corum, Beeson, & Schnellmann, 2016). In recent years, there has been an increase in published data documenting that pharmacological induction of MB restores mitochondrial and organ function following various pathological events in vivo, including SCI (Simmons, Scholpa, & Schnellmann, 2020). These findings, in conjunction with the plethora of evidence indicating that restoring mitochondrial homeostasis promotes recovery following SCI, speak to the potential for this treatment strategy. Additionally, in vitro reports have elucidated cell type-specific consequences of mitochondrial dysfunction and MB in SCI-relevant cell types, which could aid in the future development of targeted therapies.

Importantly, there exists an increasing number of U.S. Food and Drug Administration (FDA)-approved pharmaceuticals capable of MB induction, demonstrating the clinical applicability of this approach (Simmons, Scholpa, & Schnellmann, 2020). This perspective will briefly review and explore CNS cell type-specific mitochondrial dysfunction and MB, as well as describe current therapeutic strategies employing inducers of MB post-SCI.

Mitochondrial dysfunction

Mitochondrial dysfunction results from alterations to homeostatic mitochondrial processes, leading to deficient energy metabolism, primarily through decreased oxidative phosphorylation (OXPHOS) and ATP synthesis. Examples of such alterations include inadequate mitochondrial number and/or mass, altered membrane potential, mitochondrial DNA (mtDNA) mutation/fragmentation, defective electron transport chain (ETC) activity, increased production of reactive oxygen species (ROS), intracellular calcium dysregulation, and impaired mitochondrial dynamics and mitophagy (Scholpa & Schnellmann, 2017; Simmons, Scholpa, & Schnellmann, 2020).

Due to high energy demand within the CNS, mitochondrial dysfunction and ensuing loss of ATP can prevent the function of various ATPases (H^+, Ca^{2+}, Na^+/K^+-ATPase) required for effective neurotransmission, thereby deregulating cellular ion gradients. Mitochondrial dysfunction can also disrupt calcium buffering and signaling, which is crucial for neuronal synapses, leading to calcium overload and excitotoxicity (Vos, Lauwers, & Verstreken, 2010). In SCI pathology, activated astrocytes and glial cells release pro-inflammatory cytokines, resulting in mitochondrial dysfunction and ultimately apoptosis (Simmons, Scholpa, & Schnellmann, 2020). Additionally, SCI is characterized by vasculature disruption, leading to loss of blood flow and local ischemia, which contributes to oxidative stress, mitochondrial dysfunction and the propagation of cell death observed during secondary injury (Fig. 1) (Scholpa & Schnellmann, 2017). Therefore, evidence suggests that restoring mitochondrial function could be an effective strategy to mediate multiple facets of injury progression and aid in preventing further cell death.

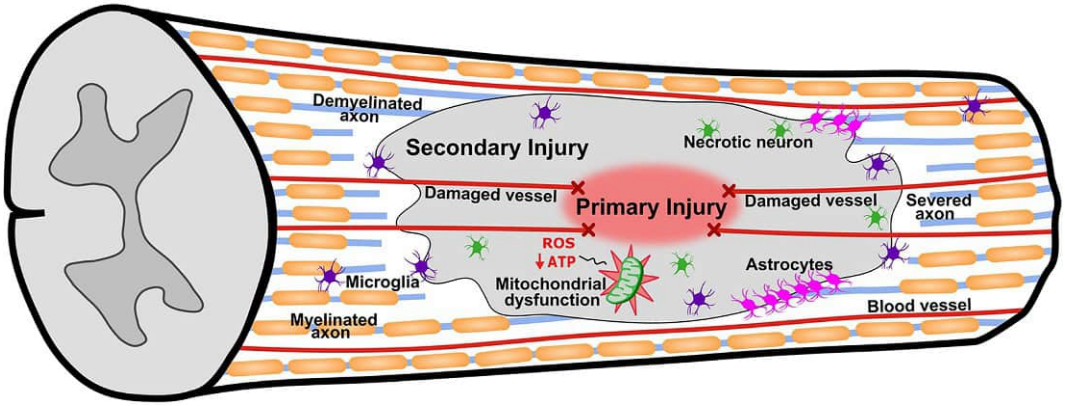

FIG. 1 Spinal cord injury pathology. Damage after spinal cord injury (SCI) is a combination of initial trauma and secondary injury. The primary injury disrupts spinal cord vasculature, reducing local oxygen delivery, decreasing mitochondrial function and adenosine triphosphate (ATP) synthesis, and increasing reactive oxygen species (ROS) production. Additional hallmarks of secondary injury after SCI include neuronal cell death, axon severing and demyelination, microglia activation and glial scar formation. *Duplicated with permission from Scholpa, N. E. & Schnellmann, R. G. (2017). Mitochondrial-based therapeutics for the treatment of spinal cord injury: Mitochondrial biogenesis as a potential pharmacological target*. The Journal of Pharmacology and Experimental Therapeutics, 363, *303–313*.

Mitochondrial biogenesis

Although many studies exist assessing mitochondria-targeted strategies for treatment of SCI, the majority address singular aspects of downstream mitochondrial dysfunction, such as increasing antioxidant defenses or inhibiting opening of the mitochondrial permeability transition pore (mPTP) (Scholpa & Schnellmann, 2017). In contrast, MB is the production of new, functional mitochondria via the growth and division of pre-existing mitochondria, which could therefore address multiple, if not all, facets of mitochondrial dysfunction (Fig. 2). This complex process involves the cooperation of multiple cellular pathways, requiring the synthesis of mtDNA, transcription and translation of mitochondrial- and nuclear-encoded proteins and ultimately assembly of ETC complexes (Whitaker et al., 2016).

Regulation of MB

Coordination of the nuclear and mitochondrial genomes is modulated by transcriptional coactivators, with the most relevant to MB being the "master regulator" peroxisome proliferator-activated receptor-gamma coactivator-1 alpha (PGC-1α) (Liang & Ward, 2006). Activation of PGC-1α can be initiated via multiple post-translational modifications, including deacetylation by sirtuin-1 (SIRT1) and phosphorylation by adenosine monophosphate-activated kinase (AMPK) and p38-mitogen-activated protein kinase (MAPK) (Ventura-Clapier, Garnier, & Veksler, 2008). Additionally, agonism of G-protein-coupled receptors (GPCRs), such as 5-hydroxytryptamine (5-HTRs) and β-adrenergic receptors (β-ARs), can activate the protein kinase B (Akt)/endothelial nitric oxide synthase (eNOS)/cyclic guanosine monophosphate (cGMP) pathway leading to activation of PGC-1α, translocation to the nucleus and, subsequently, induction of MB (Fig. 3) (Garrett, Whitaker, Beeson, & Schnellmann, 2014; Gibbs, Garrett, Beeson, & Schnellmann, 2018; Wills et al., 2012). Importantly, studies have shown that PGC-1α is decreased in the spinal cord after SCI, indicative of disrupted MB (Hu, Lang, Cao, Zhang, & Lu, 2015; Scholpa, Williams, et al., 2019).

PGC-1α regulates MB through interactions with transcription factors such as peroxisome proliferator-activated receptors (PPARs) and nuclear respiratory factors (Nrf1/2), among others (Liang & Ward, 2006; Schreiber et al., 2004). PPARs are involved in the expression of fatty acid oxidation and Krebs cycle enzymes and OXPHOS components (Lin, Handschin, & Spiegelman, 2005; Schreiber et al., 2004). Activation of Nrf1/2 induces transcription of mitochondrial transcription factor A (TFAM) (Gureev, Shaforostova, & Popov, 2019), which translocates to the mitochondria, where it activates mitochondrial gene expression and mtDNA replication (Virbasius & Scarpulla, 1994). Coordination of these transcription factors via PGC-1α culminates in the induction of MB.

Intimately related to MB is mitochondrial dynamics, namely fusion and fission. Fusion is the joining of two mitochondria mediated by mitofusins (Mfn1/2) and optic atrophy 1 (OPA1), whereas fission initiates cleavage and division of mitochondria, and is mediated, in part, by dynamin-related protein 1 (DRP1) and outer membrane receptor fission 1 (FIS1). Dysfunctional mitochondria contain impaired proteins, damaged membranes and fragmented mtDNA, increasing

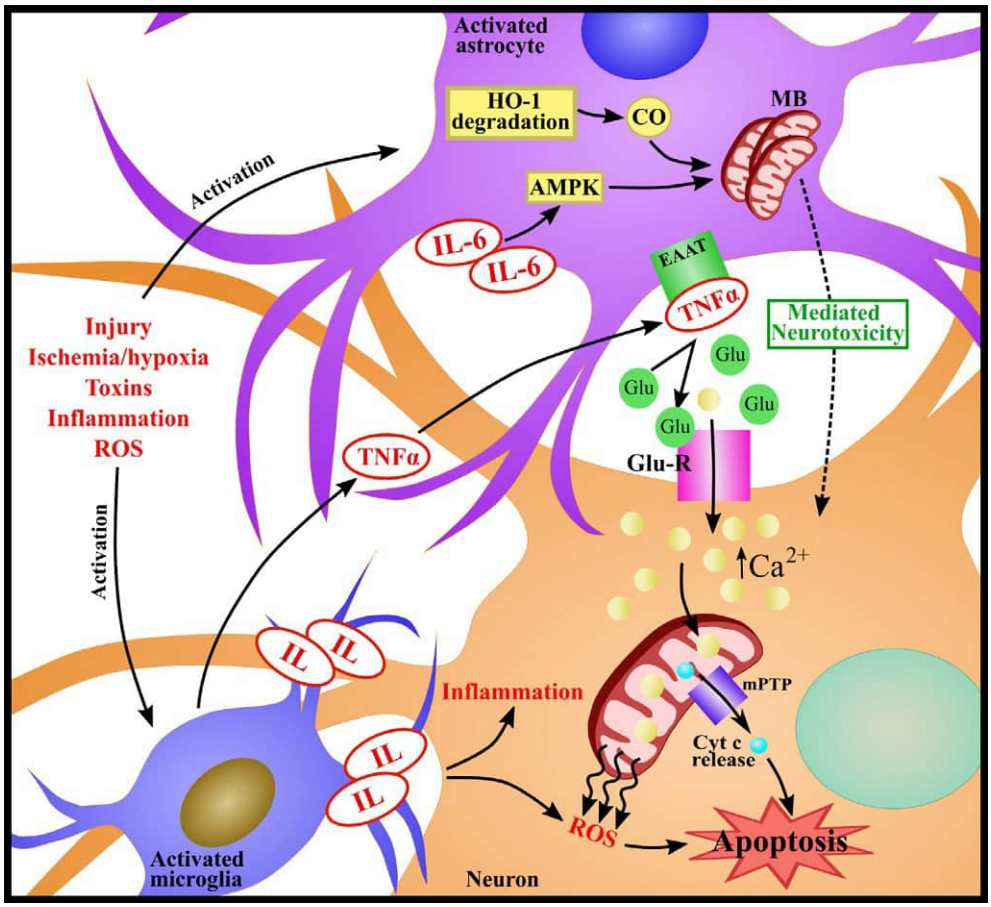

FIG. 2 Role of neuroinflammation on mitochondrial dysfunction. Various stressors can trigger activation of astrocytes and microglia, releasing cytokines and chemokines, promoting calcium overload, apoptosis and neurotoxicity. Conversely, ischemic injury increases astrocyte CO levels via HO-1 degradation. CO as well as IL-6 can promote MB and mediate neurotoxicity. fission mechanisms and mitophagy, which is the selective degradation of damaged mitochondria by autophagosomes mediated, in part, by PTEN-induced kinase 1 (PINK1) and E3-ubiquitin ligase (Parkin) interaction (Fig. 4) (Simmons, Scholpa, & Schnellmann, 2020). Conversely, promotion of fusion mechanisms has been implicated in MB and recovery (Scholpa & Schnellmann, 2017). Proper balance of MB, dynamics and mitophagy is critical for mitochondrial function and response to various stressors, including SCI.

Cell type-specific mitochondrial dysfunction and MB

SCI is a complex pathology involving heterogeneous cell types with distinct roles in the progression of injury and recovery. Many in vivo studies exist evaluating the global effects of mitochondrial-based therapies for SCI, while few reports exist detailing cell type-specific effects. Understanding the role of mitochondrial dysfunction and MB in relevant cell types can uncover not only underexplored mechanisms, but also potential therapeutic strategies following SCI.

Neurons

In addition to their primary role in bioenergetics, neuronal mitochondria contribute to regulation of synaptic transmission, calcium homeostasis, neuronal excitability and response to stress (Fanibunda et al., 2019). Neurons are dependent on efficient ATP regulation and have limited capacity to buffer oxidative stress. As such, neurons are particularly vulnerable to

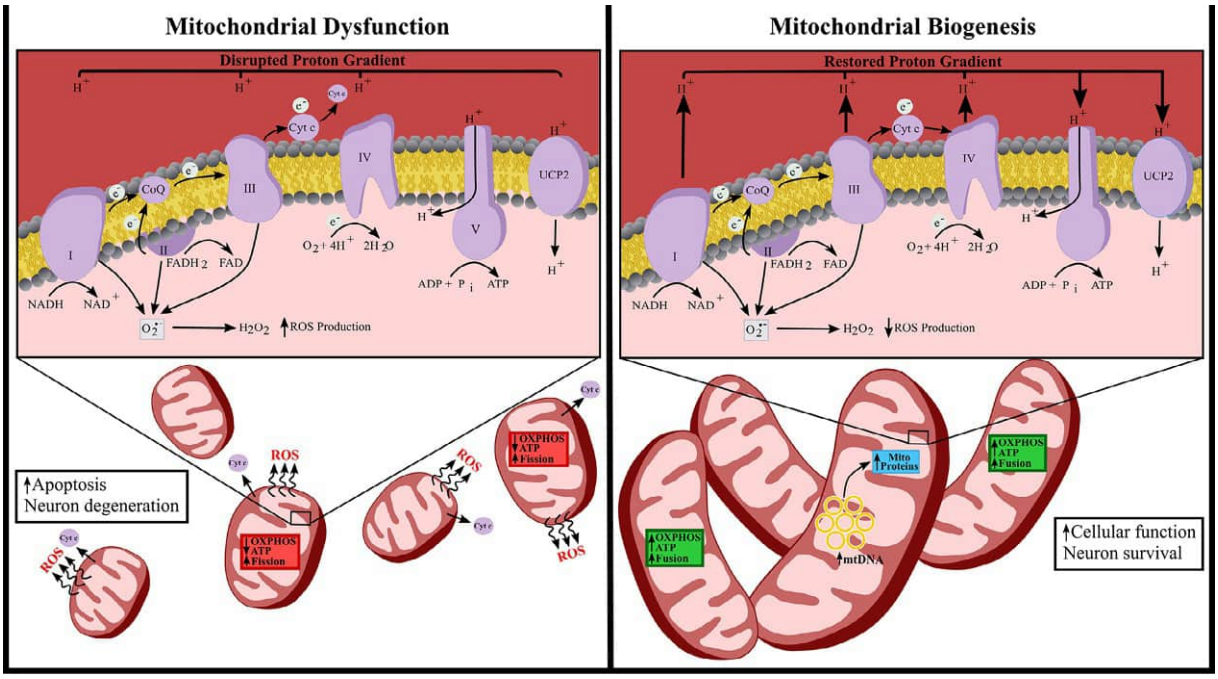

FIG. 3 Mitochondrial dysfunction and biogenesis. Mitochondrial dysfunction is characterized by decreased expression of OXPHOS proteins, impaired mitochondrial membrane potential, reduced ATP production, enhanced mitochondrial fission, ROS production and cyt *c* release. Mitochondrial dysfunction is often paired with increased apoptosis and neural degeneration. Conversely, mitochondrial biogenesis is characterized by mitochondrial fusion, reduced ROS, restoration of membrane potential and increased expression of OXPHOS proteins. CoQ, coenzyme Q; COX1, cytochrome *c* oxidase subunit 1; Cyt *c*, cytochrome *c*; e^-, electron; FAD, Flavin adenine dinucleotide; NAD^+, Nicotinamide adenine dinucleotide; O_2^-, superoxide; OXPHOS, oxidative phosphorylation; P_i, inorganic phosphate; ROS, reactive oxygen species; UCP2, uncoupling protein 2. *Modified with permission from Simmons, E. C., Scholpa, N. E., & Schnellmann, R. G. (2020). Mitochondrial biogenesis as a therapeutic target for traumatic and neurodegenerative CNS diseases.* Experimental Neurology, 329*, 113309*.

mitochondrial dysfunction, resulting in excitotoxicity, calcium overload, axon demyelination and cell death (Scholpa & Schnellmann, 2017).

In the presence of mitochondrial dysfunction in vitro, MB compounds can improve mitochondrial homeostasis and neuronal survival. For example, mitochondrial division inhibitor-1 (Mdivi-1), a DRP1 inhibitor and inducer of MB, improved mitochondrial function and neural conductance in cultured spinal cord neurons following glutamate-induced ischemia-reperfusion. Treatment also reduced oxidative stress markers, neuronal injury and apoptosis in this model (Liu et al., 2015). Serotonin, a neurotransmitter implicated in mitochondrial and functional recovery from SCI, enhanced mtDNA content, mitochondrial concentration and mitochondrial function, while demonstrating neuroprotective effects against oxidative stress in cultured rodent cortical neurons (Fanibunda et al., 2019).

MB is also implicated in stem cell differentiation and neural fate commitment. Treatment with bezafibrate, a PPAR agonist, evoked up-regulation of MB-related genes and improved cell viability, mitochondrial membrane potential and cell number during late-stage differentiation in human-induced pluripotent stem cells (Augustyniak et al., 2019). Furthermore, inherent increases in mtDNA content and MB-related gene and protein expression exist during differentiation of human neuronal stem cells (NSCs) into motor neurons (O'brien, Keeney, & Bennett Jr., 2015). NSC transplantation is being developed to promote recovery of the neural network after SCI (Zhu, Uezono, Yasui, & Nakashima, 2018); the reliance of motor neuron differentiation on MB, however, suggests that differentiating NSCs may be vulnerable to mitochondrial dysfunction after injury (O'brien et al., 2015). Therefore, concurrent treatment employing NSCs and MB compounds may enhance successful motor neuron differentiation, thereby improving NSC-induced neurogenesis and recovery post-SCI.

Astrocytes

Integral within the CNS, astrocytes maintain neuronal energy, metabolism and structural support, modulation of synaptic transmission, regulation of intercellular ion concentration, vasomodulation and promotion of the myelinating activity of

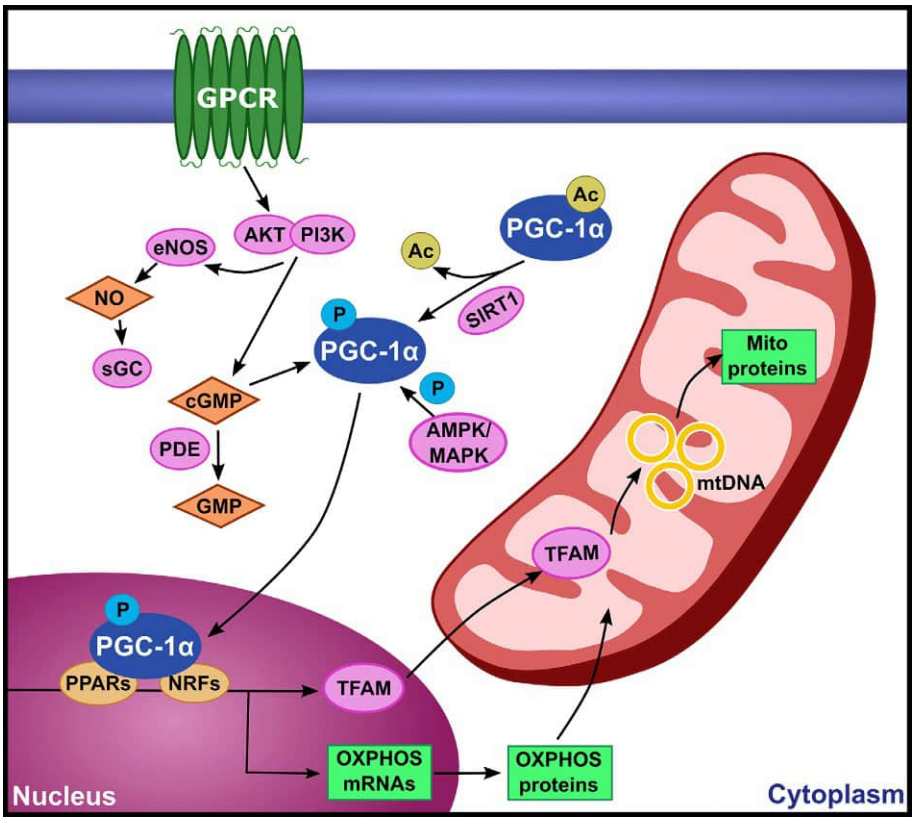

FIG. 4 Regulation of mitochondrial biogenesis. Mitochondrial biogenesis (MB) is a highly regulated process involving diverse pathways. Pharmacological agents can augment MB by targeting different aspects of these pathways, all culminating in increased expression of mitochondrial genes and MB. Ac, acetyl group; AKT, protein kinase B; AMPK, adenosine monophosphate-activated kinase; cGMP, cyclic guanosine monophosphate; eNOS, endothelial nitric oxide synthase; MAPK, mitogen activated protein kinase; mtDNA, mitochondrial DNA; NO, nitric oxide; NRF, nuclear respiratory factor; OXPHOS, oxidative phosphorylation; P, phosphate; PDE, phosphodiesterase; PGC-1α: peroxisome proliferator-activated receptor-gamma coactivator 1 alpha; PI3K, phosphoinositide-3 kinase; PPAR, peroxisome proliferator-activated receptor; sGC, soluble guanylate cyclase; SIRT1, sirtuin 1; TFAM, mitochondrial transcription factor A. *Modified with permission from Scholpa, N. The Journal of Pharmacology and Experimental Therapeutics, 363*, 303–313*.

oligodendrocytes. Following SCI, astrocytes undergo complex morphological, gene expression and functional changes (Falnikar, Li, & Lepore, 2015). Given that defects in astrocyte activity and metabolism are associated with a variety of neuropathological disorders (Choi et al., 2016), maintaining the metabolic activity of astrocytes is likely crucial for neuronal function post-SCI.

Aβ1–42, a toxic peptide aggregate found in Alzheimer's disease pathology, increases MB in astrocytes, while inducing lipid peroxidation, apoptosis and cell death in neurons. Despite these deleterious neuronal effects, increased neuronal survival, restored mitochondrial homeostasis, improved resistance to oxidative damage and modulation of the neuroinflammatory response were documented when neurons and astrocytes were co-cultured (Aguirre-Rueda et al., 2015). The neuroprotective nature of astrocytic MB reported in this study is compelling, revealing a potential therapeutic target following SCI.

Manganese (Mn) targets astrocytes and promotes the expression of pro-inflammatory cytokine interleukin-6 (IL-6) and tumor necrosis factor alpha (TNFα), leading to mitochondrial dysfunction and neurotoxicity in vitro. In mouse cerebral astrocytes, Mn-induced inflammation led to decreased mitochondrial mass, excessive fission, as well as impaired basal and ATP-linked mitochondrial respiration (Sarkar et al., 2018). Interestingly, the antioxidant mito-apocynin attenuated this inflammatory response and restored mitochondrial mass (Sarkar et al., 2018). While Mn toxicity is often observed following occupational or environmental exposure (Harischandra et al., 2019), this impaired astrocytic mitochondrial profile presents similarly to that following SCI (McAvoy & Kawamata, 2019). As such, future studies should investigate the therapeutic potential of mito-apocynin in mediating astrocytic dysfunction following SCI.

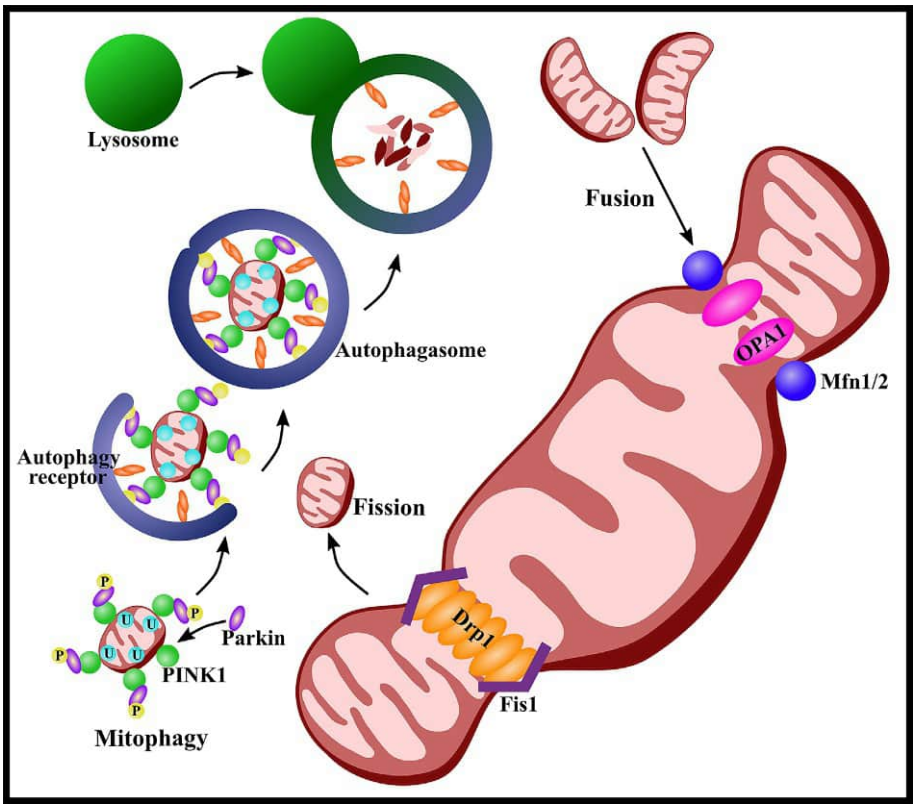

FIG. 5 Mitochondrial dynamics. Mitochondrial fusion is mediated by outer (Mfn1/2) and inner membrane (Opa1) proteins. Fission is initiated by recruitment of DRP1 to the mitochondrial membrane, where it interacts with receptors (Fis1), inducing membrane splitting. Excessive fission may promote mitophagy, which is activated by destabilization of PINK1, which recruits, phosphorylates (P) and activates Parkin, promoting the formation of autophagosomes, which will fuse with a lysosome leading to degradation. Drp1, dynamin-related protein 1; Fis1, fission 1; Mfn1/2, mitofusin 1/2; OPA1, optic atrophy 1; PINK1, PTEN-induced kinase 1. *Duplicated with permission from Simmons, E. C., Scholpa, N. E., & Schnellmann, R. G. (2020). Mitochondrial biogenesis as a therapeutic target for traumatic and neurodegenerative CNS diseases.* Experimental Neurology, 329*, 113309*.

In addition to pharmacological induction, internally driven MB can occur as a programmed response to aid in the recovery of astrocytes following oxidative insults (Fig. 5) (Chen et al., 2018; Choi et al., 2016). Oxidant injuries stimulate the expression of heme oxygenase-1 (HO-1) in astrocytes. Carbon monoxide (CO), a by-product of HO-1-driven heme degradation, regulates energy metabolism and can mitigate tissue injury and inflammation in neurological diseases. In addition, HO-1-derived CO increases MB, as evidenced by increased PGC-1α and ATP synthesis in astrocytes (Choi et al., 2016). Therefore, astrocytic HO-1 induction during ischemic events may be endogenously protective via stimulation of MB, thereby hindering propagation of ischemic damage. Furthermore, reports demonstrate that endogenous and exogenous CO can promote MB in cerebral astrocytes in vitro (Piantadosi, Carraway, Babiker, & Suliman, 2008). As such, CO-mediated MB in astrocytes may be protective following SCI.

In cultures of rat cerebral astrocytes, septic conditions induced neuroinflammation and triggered protective mechanisms to increase MB and ATP at early time points. Additionally, treatment with IL-6, a cytokine mainly produced by astrocytes, enhanced MB through IL-6/AMPK signaling under septic conditions (Chen et al., 2018), suggesting that astrocyte-specific MB in the presence of neuroinflammation may intrinsically combat mitochondrial dysfunction and promote recovery. Although increased IL-6 levels following SCI are considered inherently negative, future studies should explore the potential neuroprotective effects of astrocytic IL-6-induced MB following injury.

Endothelial cells

Endothelial cells are integral components of the blood–spinal cord barrier (BSCB) and are specifically organized to facilitate selective permeability, limiting blood-derived molecules from entering the spinal cord. SCI often results in catastrophic destruction of the BSCB, leading to enhance permeability and allowing neuroinflammation to propagate secondary injury. Conversely, angiogenesis and restoration of BSCB integrity has been associated with improved

pathological and behavioral outcomes. Mitochondrial quality control mechanisms, including mitochondrial dynamics and mitophagy, are needed to maintain angiogenic and vasodilator functions of endothelial cells (Kluge, Fetterman, & Vita, 2013). Though mitochondrial content in endothelial cells is relatively modest, angiogenesis is an energy-demanding process essential for SCI recovery and has been closely linked to MB pathways (Kluge et al., 2013; Kumar, Ropper, Lee, & Han, 2017). A comprehensive review detailing key aspects of mitochondrial function in the endothelium can be found in Kluge et al. (2013) and Eelen et al. (2018).

Therapeutic strategies targeting increased activity of PGC-1α and AMPK consistently demonstrate improved endothelial function. The glycolysis inhibitor 2-deoxyglucose activates AMPK, inducing autophagy and protecting against cell death of endothelial cells in vitro (Kluge et al., 2013). In addition, thiazolidinediones reduce ROS while activating PGC-1α and MB in endothelial cells (Kluge et al., 2013). Metformin, an inhibitor of IL-1β and activator of AMPK, impedes mPTP opening and endothelial apoptosis, thereby preventing endothelial dysfunction (Kluge et al., 2013). Resveratrol also induces MB and reduces hydrogen peroxide levels of endothelial cells in culture (Kluge et al., 2013). These studies suggest that MB strategies may increase recovery following SCI, in part by improving mitochondrial function in the endothelium. In support of this, pharmacological activation of MB following SCI has been shown to improve BSCB integrity, correlating with enhanced recovery in vivo (Simmons, Scholpa, Cleveland, & Schnellmann, 2020).

Mitochondrial biogenesis mediates consequences of SCI

Mitochondrial homeostasis and functional recovery

PGC-1α is decreased in the injured spinal cord in rodent contusion SCI models (Hu et al., 2015; Hu, Lang, Zhang, Ni, & Lu, 2016; Scholpa, Williams, et al., 2019), indicating loss of mitochondrial function and decreased MB. Lentiviral overexpression of PGC-1α in the injured cord has been shown to decrease neuronal cell death and improve recovery (Hu et al., 2015, 2016). Furthermore, treatment with pharmacological agents that induce PGC-1α expression have similar restorative effects (Hu et al., 2015; Scholpa, Williams, et al., 2019; Simmons, Scholpa, Cleveland, et al., 2020).

Tetramethylpyrazine (TMP), a plant extract, is neuroprotective following SCI in rats via induction of PGC-1α and MB, leading to improved locomotor capability and decreased neural apoptosis (Hu et al., 2015). Treatment with the β_2-AR agonist formoterol beginning 8 h post-SCI increased PGC-1α and downstream protein expression in the injured cord, improved locomotor function and decreased lesion volume in a mouse contusion SCI model (Scholpa, Simmons, Tilley, & Schnellmann, 2019; Scholpa, Williams, et al., 2019). Daily administration of the 5-HT_{1F} receptor agonist LY344864 after SCI similarly increased PGC-1α expression, as well as improved markers of functional recovery and decreased BSCB leakage (Simmons, Scholpa, Cleveland, et al., 2020). Of note, formoterol is FDA-approved for the treatment of asthma and the 5-HT_{1F} receptor agonist lasmiditan was recently approved for the treatment of migraines (Lamb, 2019), indicating the potential applicability of this SCI treatment strategy.

Body composition

In addition to local dysfunction in the spinal cord, SCI can decrease peripheral mitochondrial activity, with decreased mitochondrial size, protein expression and function reported in skeletal muscle after injury (Mccully, Mulcahy, Ryan, & Zhao, 2011; Scelsi, Marchetti, Poggi, Lotta, & Lommi, 1982). Paralysis following SCI can lead to disuse atrophy and rapid loss of skeletal muscle function and metabolic activity, which can increase the risk of developing metabolic diseases such as type II diabetes (Gorgey et al., 2019; O'brien & Gorgey, 2016). In fact, while pneumonia and septicemia are the leading causes of death post-SCI, mortality rates for metabolic and musculoskeletal disorders are on the rise (National Spinal Cord Injury Statistical Center, 2020).

Besides its canonical role as an inducer of MB, PGC-1α is also involved in activation of muscle hypertrophy and downregulation of atrophy (Qin, Pan, Wu, Bauman, & Cardozo, 2010; Scholpa, Simmons, et al., 2019). Therefore, induction of PGC-1α and increased MB can address multiple SCI-induced deficits. In support of this, exercise training induces PGC-1α in the skeletal muscle of rodents and humans (Baar et al., 2002; Pilegaard, Saltin, & Neufer, 2003), and increases mitochondrial mass and function in paralyzed muscle (O'brien & Gorgey, 2016). Transgenic overexpression of PGC-1α has also been found to protect against muscle atrophy and promote MB (Dinulovic et al., 2016; Sandri et al., 2006). In addition to improving functional recovery, daily formoterol treatment after SCI increased gastrocnemius muscle mass, corresponding to increased hypertrophy and decreased expression of atrophy markers in mice (Scholpa, Simmons, et al., 2019). Formoterol treatment also restored body weight to that of pre-injury (Scholpa, Simmons, et al., 2019), indicating reestablishment of body composition, which is fundamentally altered following SCI.

Axonal growth

Limited recovery within the spinal cord post-SCI is largely due to lack of axonal growth (Meves & Zheng, 2014). In addition to axons' poor intrinsic growth capabilities, the presence of growth-inhibiting molecules and lack of growth-promoting factors make the CNS environment unconducive to axonal growth after injury. Unfortunately, while multiple attempts have been made to encourage axonal growth, success has been limited (Meves & Zheng, 2014). Neuronal growth requires a substantial amount of energy to not only synthesize the necessary substrates, but also transport these substrates to distal axonal locations. PGC-1α has been demonstrated to regulate mitochondrial density and energy production in both neuronal cell bodies and axons (Wareski et al., 2009). Overexpression of PGC-1α led to a twofold increase in total number of mitochondria in axons, particularly in the distal end furthest from the cell body, corresponding with axonal growth acceleration (Vaarmann et al., 2016). Additionally, suppression of PGC-1α also suppresses neuronal growth, further solidifying the relationship between axonal growth and MB (Vaarmann et al., 2016).

Inflammation

Mitochondria are integral to regulating innate immunity and the inflammatory response (Mohanty, Tiwari-Pandey, & Pandey, 2019) and as such, inflammatory disorders are associated with mitochondrial dysfunction (Missiroli et al., 2020). Within 15 min, SCI initiates inflammation, which plays a central role in the regulation of secondary injury (Zhang, Yin, Xu, Wu, & Chen, 2012). Inflammation can lead to neuron and oligodendrocyte apoptosis, formation of the glial scar and ultimately loss of neuronal function (Zhang et al., 2012). Therefore, it is hypothesized that mitigating inflammation could limit secondary injury progression.

During early inflammation, mitochondrial dysfunction is induced by pro-inflammatory cytokines such as TNFα and interleukins (Cherry & Piantadosi, 2015), with the degree of mitochondrial dysfunction being roughly correlated with clinical outcomes and recovery in humans and rodents (Brealey et al., 2004; Cherry & Piantadosi, 2015). Restoration of mitochondrial function and homeostasis is dependent upon rapid induction of quality control mechanisms, such as MB (Cherry & Piantadosi, 2015). In fact, activation of the inflammatory pathway directly impacts mitochondrial function via up-regulation of MB (Fernandez-Marcos & Auwerx, 2011). Inflammatory receptors activate multiple pathways within a cell, including MAPK and Akt pathways, which in turn lead to the activation of activating protein-1 (AP-1) and p38, ultimately increasing PGC-1α (Cherry & Piantadosi, 2015; Fernandez-Marcos & Auwerx, 2011). Additionally, Akt phosphorylates Nrf1, which induces TFAM activation and the transcription of MB genes (Cherry & Piantadosi, 2015).

While long-term respirometric dysfunction is unsuitable for cell survival, early inflammation-induced mitochondrial dysfunction may be advantageous, attenuating ROS production and decreasing ATP availability, preventing the appropriation of host cell energetics and, ultimately, the spread of infection (Cherry & Piantadosi, 2015). Furthermore, macrophages and microglia have been suggested to be neuroprotective after injury, and complete depletion of neutrophils severely impairs functional recovery after SCI (Okada, 2016; Rust & Kaiser, 2017). Additionally, TNFα signaling appears to be necessary for remyelination (Arnett et al., 2001), and certain parts of the glial scar have been shown to support axon regeneration post-SCI (Anderson et al., 2016). Consequently, therapeutic strategies aimed at mitigating inflammation after SCI via MB induction must take into consideration the potential benefit of the inflammatory response.

Importantly, recent evidence indicates that the SCI-induced inflammatory response is not exclusive to the spinal cord, but is systemic, leading to widespread organ damage (Sun et al., 2016). Treatment with the mitochondrial-targeted peptide SS-31 improved mitochondrial function, controlled the inflammatory response and alleviated lung damage in a mouse model of SCI (Zhu, Li, He, Zhou, & Jiang, 2017). Therefore, systemic pharmacological induction of MB has the potential to mitigate widespread inflammation following SCI.

Limitations of MB

While MB can aid in restoring cellular homeostasis and recovery from injury, limitations do exist. Many disease pathologies, including SCI, present a heterogeneous mix of mitochondrial health, particularly at early stages of disease progression. Although pre-clinical models have consistently demonstrated MB induction can attenuate mitochondrial dysfunction and improve recovery, there exists no way to selectively target healthy mitochondria for replication. As such, MB induction within dysfunctional mitochondria may propagate replication of mutated mtDNA, resulting in increased injury severity and disease progression (Simmons, Scholpa, & Schnellmann, 2020).

Applications to other areas of neuroscience

Considering central nervous system (CNS) function is highly dependent on mitochondrial homeostasis and energetics, it is unsurprising that brain and spinal cord systems are sensitive to mitochondrial dysfunction (Golpich et al., 2017). Both acute and neurodegenerative diseases are characterized by mitochondrial dysfunction and impaired mitochondrial biogenesis (MB). This dysregulation often leads to defective electron transport chain function and reduced adenosine triphosphate production, thereby promoting neuronal death. Remarkably, pharmacological activation of MB has been shown to restore mitochondrial function and homeostasis, and promote recovery across a variety of CNS pathologies (Table 1). MB-related therapies have proven efficacious in restoring mitochondrial homeostasis and cognitive capabilities across pre-clinical models of injury, including stroke and traumatic brain injury (Gibbs, Scholpa, Beeson, & Schnellmann, 2018; Simmons, Scholpa, & Schnellmann, 2020). In addition, mitochondrial dysfunction and MB is well-studied in neurodegenerative diseases including Alzheimer's disease, Parkinson's disease, amyotrophic lateral sclerosis, Huntington's disease and multiple sclerosis, with several known MB-inducing pharmaceuticals currently in clinical trials (Gibbs, Scholpa, et al., 2018; Hayashi et al., 2017; Simmons, Scholpa, & Schnellmann, 2020). As such, attenuation of mitochondrial dysfunction through induction of MB is an encouraging therapeutic strategy in several areas of neuroscience. For comprehensive reviews detailing MB in traumatic and neurodegenerative diseases, see Golpich et al. (2017), Sebastian, Palacin, and Zorzano (2017), and Simmons, Scholpa, and Schnellmann (2020).

TABLE 1 Partial list of pharmacological inducers of MB for the treatment of CNS-related diseases.

Disease	Mitochondrial dysfunction	Tested MB treatments
ACUTE/TRAUMATIC		
Spinal Cord Injury	↓mitochondrial homeostasis ↑mtDNA mutations/fragmentation ↓OXPHOS proteins ↓ATP synthesis ↓ATP-dependent cellular processes ↓Ion homeostasis ↑mitophagy ↑Oxidative damage ↓Calcium buffering ↑mPTP opening ↑Cell death	**Formoterol**: ↑PGC-1α: ↓cell death, ↑function **LY344864**: ↑PGC-1α: ↓cell death, ↑function
Traumatic Brain Injury		**Quercetin**: ↑PGC-1α, ↓cell death **DEX**: ↑PGC-1α, ↓cell death, ↑behavior **7,8-DHF**: ↑PGC-1α, ↑function **SS-31**: ↑PGC-1α, ↑function, ↑behavior
Stroke		**Daidzein**: ↓cell death, antioxidant **Metformin**: ↓cell death, ↑behavior **Melatonin**: ↑mitophagy, antioxidant **Resveratrol**: ↑neuron survival
CHRONIC/NEURODEGENERATIVE		
Alzheimer's Disease	↓mitochondrial homeostasis ↑mtDNA mutations/fragmentation ↓OXPHOS proteins ↓ATP synthesis ↓mitophagy ↑Oxidative damage ↑Cell death	**TZDs**: ↑behavior **Resveratrol**: ↑PGC-1α, ↑behavior, ↑pAKT **AICAR**: ↑behavior, ↑pAKT **Melatonin**: ↑PGC-1α, ↑function, ↓Aβ
Parkinson's Disease		**Bezafibrate**: ↑PGC-1α, ↑behavior **Resveratrol**: ↑PGC-1α, ↑function, ↓cell death **LY344864**: ↑PGC-1α, ↑function, ↓cell death **Triterpenoids**: ↑Nrf2, antioxidant
Huntington's Disease		**Resveratrol**: ↑function, ↓cell death
Amyotrophic lateral sclerosis		**Resveratrol**: ↑function, ↓cell death
Huntington's Disease		**Resveratrol**: ↑function, ↓cell death
Multiple Sclerosis		**Dimethyl fumarate**: ↑Nrf2, ↑function **Metformin**: ↑AMPK, ↑function

Arrows indicated increase (↑) and decrease (↓). AMPK, adenosine monophosphate-activated kinase; mPTP: mitochondrial permeability transition pore; mtDNA, mitochondrial DNA; Nrf2, nuclear respiratory factor 2; OXPHOS, oxidative phosphorylation; pAKT, phosphorylated protein kinase B; PGC-1α: peroxisome proliferator-activated receptor-gamma coactivator 1 alpha.

Mini-dictionary

- Oxidative Phosphorylation: Metabolic pathway involving mechanisms on the inner mitochondrial membrane including electron transport chain activity to produce adenosine triphosphate.
- Mitochondrial Dysfunction: Disruption of mitochondrial homeostasis, including impairment of oxidative phosphorylation, reduced mitochondrial number and mass, altered membrane potential, intracellular calcium dysregulation and mutated/fragmented mitochondrial DNA.
- PGC-1α: The master regulator of mitochondrial biogenesis, co-activates the transcription of several genes necessary for mitochondrial function.
- Mitophagy: Selective degradation of mitochondria by autophagy.
- Mitochondrial Biogenesis: Complex process by which cells increase mitochondrial mass and function.
- Mitochondrial Dynamics: Morphological cycles of fission and fusion executed by mitochondria, crucial for maintenance of function.
- Neuroinflammation: Inflammation of the nervous system as a response to stressors, such as injury.
- Oxidative Stress: Imbalance between free radicals and antioxidants often present after a traumatic injury such as spinal cord injury.
- Neurotoxicity: Damage caused by endogenous or exogenous neurotoxins resulting in altered activity of the nervous system and neuronal death.
- Ischemia: Local impairment of perfusion often propagating biological dysfunctions including mitochondrial dysfunction and cell death.

Key facts

Activation of mitochondrial biogenesis (MB) restores mitochondrial function in spinal cord injury-related cell types:

- Protects against oxidative stress and improves mitochondrial function in neurons
- Prevents neuronal injury and improves neuronal conductance and cell survival
- Mediates pro-inflammatory assaults and resulting neurotoxicity in astrocytes
- Protects against mitochondrial dysfunction while promoting endothelial cell survival
- Internally driven astrocytic mitochondrial biogenesis can be a programmed response to oxidative stress, hindering propagation of ischemic damage

Pharmacological activation of MB promotes recovery of mitochondrial homeostasis and function after spinal cord injury:

- Improves mitochondrial dynamics and mitophagy
- Restores mitochondrial composition and oxidative buffering capacity
- Recovers mitochondrial respiration and adenosine triphosphate production
- Mediates inflammatory response and neurotoxicity
- Improves blood–spinal cord barrier integrity
- Promotes axonal growth and myelination
- Improves body composition
- Improves locomotor capabilities

Summary points

- Mitochondrial dysfunction is a hallmark of spinal cord injury (SCI), propagating the progression of secondary injury, neuronal cell death and loss of function.
- Mitochondrial biogenesis inducers restore mitochondrial function in cultures of CNS-derived neurons, astrocytes and endothelial cells.
- Pharmacological activation of mitochondrial biogenesis mitigates several consequences of SCI including axonal regeneration, blood–spinal cord barrier integrity, altered body composition and locomotor capabilities in pre-clinical models of SCI.
- Therapies targeting mitochondrial biogenesis induction promote functional recovery across multiple traumatic and neurodegenerative CNS-related diseases.
- Several FDA-approved pharmaceuticals can induce mitochondrial biogenesis; therefore, repurposing these compounds for SCI treatment could be a relatively expeditious process.

List of abbreviations

COX	cyclooxygenase
GSH	glutathione
IL-1α	interleukin-1α
IL-1β	interleukin-1β
iNOS	inducible nitric oxide synthase
L/D	light/dark
L/L	light/light
LPO	lipid peroxidation
MDA	malondialdehyde
MT	melatonin
NF-κB	nuclear factor-κB
NG-2	neuron/glial antigen 2
SCI	spinal cord injury
SOD	superoxide dismutase
TBI	traumatic brain injury
TNF-α	tumor necrosis factor-α

Introduction

Spinal cord injury (SCI) is a catastrophic incident with a global mortality rate ranging from 4.4% to 16.7%, often leading to neurological disability (Yamazaki, Kawabori, Seki, & Houkin, 2020). Traumatic injury to the spinal cord induces death in a number of local neurons and glia at the lesion site that cannot be recovered or regenerated. The mechanisms of secondary injury begin immediately after the primary insult and continue for weeks or months via a diverse array of pathophysiological processes, including inflammation, excitotoxicity, and oxidative cell damage (Alizadeh, Dyck, & Karimi-Abdolrezaee, 2019). These secondary insults lead to further destruction of neuronal and glial cells and to massive extension of the damage whereby the paralysis can extend to higher segments.

Disruption of circadian rhythm is a common feature in SCI individuals. Circadian misalignment can increase neuronal death, resulting in deterioration of sensorimotor functions and cognitive deficits (Li et al., 2016). In experimental studies, SCI was shown to lead to wide-ranging circadian rhythm disruption, including dysregulated rhythms of body temperature, and inflammatory gene expression (Gaudet et al., 2018). Besides, circulating levels of serum melatonin (MT) has been altered in patients with cervical SCI (Fatima, Sharma, & Verma, 2016), suggesting alteration of diurnal rhythms negatively influencing the SCI recovery process.

As SCI results in permanent or long-term disability and poor quality of life, it imposes an enormous financial burden on society in terms of increased healthcare costs and decreased productivity (Chan, Cadarette, Wodchis, Krahn, & Mittmann, 2019). Although efforts are currently being pursued to develop novel therapeutics to combat the pathogenesis of SCI, the

Diagnosis and Treatment of Spinal Cord Injury. https://doi.org/10.1016/B978-0-12-822498-4.00029-4

effects of these interventions are generally limited. For example, exercise interventions, which are widely used to improve functional recovery following SCI, have an inadequate ability to improve motor function after SCI (Petrosyan, Alessi, Hunanyan, Sisto, & Arvanian, 2015).

MT is a neurohormone that is synthesized and released from the pineal gland in a 24-h diurnal pattern and exerts its actions in peripheral tissues. This pineal hormone is best known for maintaining the 24-h internal clock and has excellent antioxidant capacity (Sumsuzzman, Choi, Khan, & Hong, 2020). MT exerts beneficial effects by altering the levels of oxidative stress markers, including malondialdehyde (MDA), glutathione (GSH), superoxide dismutase (SOD), and myeloperoxidase, which are generally reported to show abnormalities with progression of SCI (Aghazadeh, Azarnia, Shirazi, Mahdavi, & Zangii, 2007; Erten et al., 2003). MT has other biological functions in SCI, including reduction of pro-inflammatory molecules (Zhang et al., 2019) and regulation of autophagy (Li et al., 2019). Recently, we demonstrated that a significant reduction in endogenous MT levels disrupted neural remodeling, and homeostasis of endogenous MT levels contributed to excitatory synaptic formation and axonal outgrowth in a rodent model of SCI (Hong et al., 2019), indicating MT replacement strategies improve the neuronal repair process following SCI.

In this chapter, we explore the promising molecular mechanisms of MT intervention that may be beneficial in the management of SCI. We discuss MT and exercise combination therapy in SCI. Finally, we also discuss the crucial role of endogenous MT, which may influence the recovery process after SCI.

Effects of exogenous melatonin on secondary injury after spinal cord injury

Neuronal death caused by primary injury from SCI cannot be prevented. Therefore, current research focuses on preventing the secondary injury cascade to mitigate progressive tissue damage, representing a novel strategy for the management of SCI pathology. The timeline of major pathological events of secondary injury and timeline-specific therapeutic strategies are shown in Fig. 1. In this section, we will discuss recent findings on the effects of exogenous MT on SCI, particularly the neuroprotective mechanism of action of MT in secondary injury events.

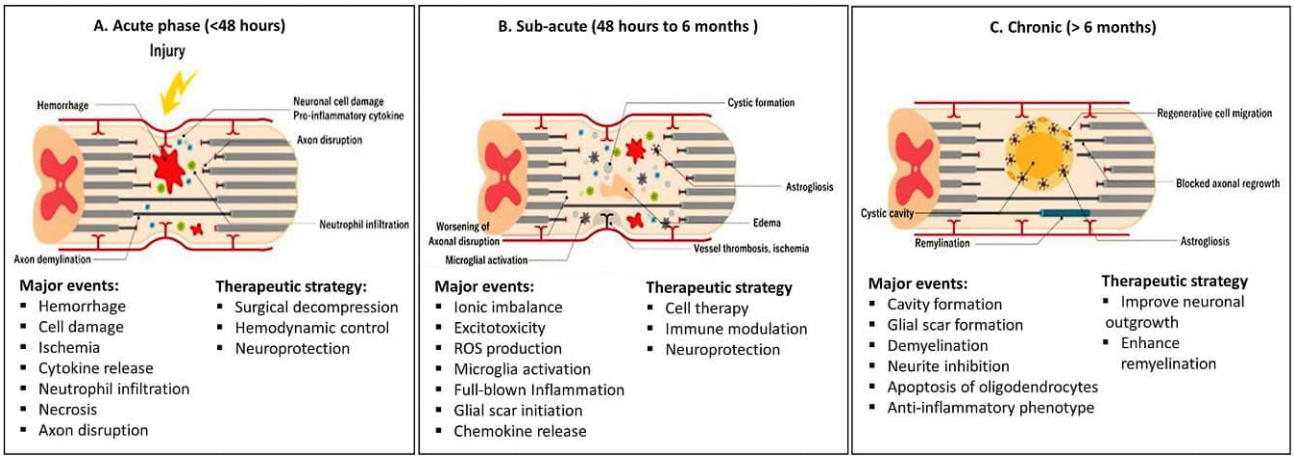

FIG. 1 Timeline of the major pathological events after spinal cord injury (SCI) and the best therapeutic strategies for SCI. The secondary injury mechanisms are initiated after the primary insult and sustained over a long period. The events that occur after primary insults are divided into the acute (<48 h), sub-acute (2 days–6 months), and chronic (>6 months) phases. (A) In the acute phase, hemorrhage, ischemia, and edema cause cell dysfunction and death. In addition, the inflammatory cells infiltrate into the injured spinal cord, resulting in the release of pro-inflammatory cytokines. These excessive inflammatory mediators can disrupt the blood-spinal cord barrier, further exacerbating the injury. (B) In the sub-acute phase, glutamate excitotoxicity, excessive ROS generation, and the full-blown inflammatory response cause further cell death and damage to the spinal cord architecture. Importantly, glial scar formation initiates this phase. (C) In the chronic phases, axons continuously degenerate, and the glial scar matures, inhibiting the neuronal regeneration process. The inflammatory phenotype shifts from pro-inflammatory to anti-inflammatory in this phase. Cavity formation also appears, which suppresses axonal regrowth. During the acute and sub-acute phases of SCI, multiple pathological cascades trigger the cell death process, leading to greater damage than that caused by the primary insult. Therefore, the pathophysiological events associated with the acute and sub-acute phases are the ultimate targets for therapeutic interventions. *ROS*, reactive oxygen species; *SCI*, spinal cord injury. *(Reprinted from Yamazaki, K., Kawabori, M., Seki, T., & Houkin, K. (2020). Clinical trials of stem cell treatment for spinal cord injury.* International Journal of Molecular Sciences, 21, *3994. According to the Creative Commons License (CC-BY-NC-ND).)*

Effects of exogenous melatonin on oxidative stress

Pre-clinical research in animal models has reported that increased production of reactive oxygen species (ROS) and the consequent oxidative stress are crucial pathological events in SCI, which lead to neurological deficits. Oxidative stress is a hallmark of the secondary injury in SCI. Much of the current literature on secondary injury after SCI has focused particularly on oxidative stress because down-regulation of its detrimental effects is considered a key strategy for therapeutic interventions (Cristante, de Barros Filho, Marcon, Letaif, & da Rocha, 2012). After SCI, oxidative stress may increase the level of lipid peroxidation (LPO) (McDonald & Sadowsky, 2002), as determined by quantifying the levels of MDA, GSH, and SOD. Electron resonance spectrometry was used to measure MDA levels and provided the first lines of evidence for ROS production in SCI. Seligman et al. (1977) reported that the level of MDA was significantly increased within the first 5 h following SCI. A recent study showed that the MDA level increased markedly after 1 day and peaked at 7 days after SCI (Song et al., 2013). SOD activity was decreased at 1 day following SCI (Song et al., 2013). Previous studies showed that MT and its derivatives scavenge free radicals and induce the activities of various antioxidant enzymes. Erşahin et al. (2012) investigated the impact of MT in a rat model of standard weight drop-induced moderate SCI and showed that MT significantly restored the MDA and GSH levels. Immediately after laminectomy, treatment of SCI rats with MT once daily for 10 days also resulted in restored GSH levels (Erol et al., 2008). In addition, the pathophysiological mechanism was proposed to involve iron-catalyzed LPO contributing to autodestruction in the injured spinal cord regions (Emerit, Beaumont, & Trivin, 2001). Previous research established that ferrous iron can initiate brain LPO (Behrmann, Bresnahan, Beattie, & Shah, 1992). After SCI, the levels of free iron and MDA were significantly increased but markedly decreased by MT treatment (Liu, Tang, Yang, & Xiao, 2004). Topsakal et al. (2003) investigated the effects of MT, prostaglandin E1, and oxytetracycline on LPO and antioxidant activities in an experimental model of SCI. The results showed that experimentally induced SCI reduced erythrocyte SOD and plasma GSH activities and increased tissue and blood MDA levels (Topsakal et al., 2003). These physiological alterations were inhibited by MT, prostaglandin E1, and oxytetracycline treatments to varying degrees, with MT showing the greatest effect (Topsakal et al., 2003). Taken together, pre-clinical trials suggest that MT may exert neuroprotective effects on SCI by reducing oxidative stress and promoting functional recovery after SCI (Fig. 2).

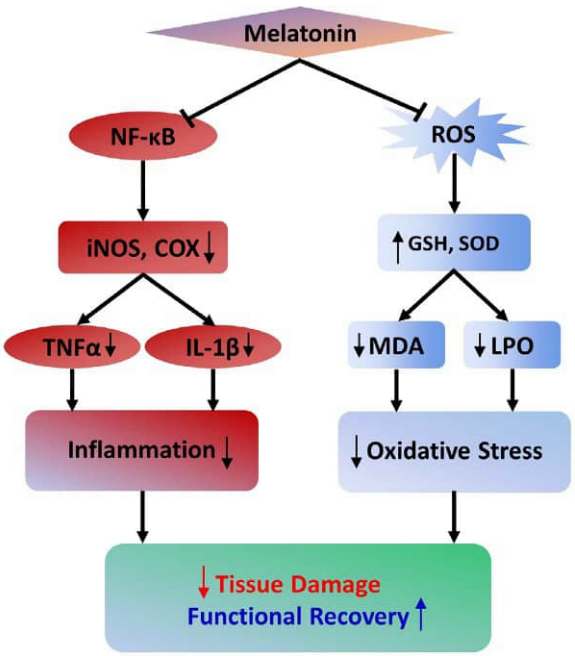

FIG. 2 Schematic representation of the potential mechanisms of action of melatonin in spinal cord injury. Increased production of ROS, MDA, LPO, and consequent oxidative stress is a crucial pathological event in SCI. Melatonin can scavenge free radicals, increase the levels of antioxidant enzymes such as SOD and GSH, and reduce the levels of MDA and LPO following SCI. Moreover, inflammation can directly promote tissue damage and weaken functional recovery after SCI by generating a wide array of inflammatory molecules. However, exogenous melatonin can reduce the levels of inflammatory molecules, such as TNF-α and IL-1β, possibly by inhibiting NF-κB. Melatonin also reduces the expression of iNOS and COX. *COX*, cyclooxygenase; *IL-1β*, interleukin-1β; *iNOS*, nitric oxide synthase; *LPO*, lipid peroxidation; *SOD*, superoxide dismutase; *GSH*, glutathione; *MDA*, malondialdehyde; *NF-κB*, nuclear factor-κ light chain enhancer of activated B cells; *ROS*, reactive oxygen species; *SCI*, spinal cord injury; *TNF-α*, tumor necrosis factor-α.

Effects of exogenous melatonin on inflammation

Within a few hours following SCI, pro-inflammatory cytokines, such as interleukin (IL)-1α, tumor necrosis factor-α (TNF-α), and IL-1β, are activated (Ritz & Hausmann, 2008). After SCI, up-regulation of inducible nitric oxide synthase (iNOS) results in excessive production of nitric oxide (NO), which is abundant in astrocytes and microglial cells (Conti et al., 2007). These excessive levels of NO further stimulate the synthesis of several pro-inflammatory cytokines (Conti et al., 2007). These pro-inflammatory molecules are associated with activation of local microglia and astrocytes, which promote secondary injury after SCI. Several studies have postulated that MT may contribute to reduced inflammation after SCI. Previously, our group reported that iNOS mRNA expression was significantly lower in the MT treatment groups than SCI groups in the region of the injured spinal cord (Park et al., 2010). Moreover, a recent study showed that treatment with MT markedly inhibited the accumulation and proliferation of microglia and astrocytes in the injured spinal cord and suppressed TNF-α, IL-1β, and iNOS expression after SCI (Yang, Bao, Chen, & He, 2020). Those findings may explain the cellular and molecular mechanisms by which MT exerts its neuroprotective effects and contributes to functional recovery after SCI. In a mouse model of severe crush SCI, the inflammatory response appeared to be significantly attenuated at 14 days after MT treatment (10 mg/kg) (Krityakiarana et al., 2016). Immunohistochemical analysis also showed that MT treatment markedly reduced IL-1β and neuron/glial antigen 2 levels (Krityakiarana et al., 2016). The results of that study suggested that MT can decrease the expression and release of pro-inflammatory molecules, thereby inhibiting tissue damage from the secondary inflammatory response. Furthermore, TNF-α may play a pivotal role in the acute phase of SCI. Haddadi and Fardid (2015) conducted a study in radiation-induced SCI rats to assess the efficacy of MT on TNF-α expression and reported that TNF-α expression was markedly increased in the irradiated group compared with the normal group 3 weeks after injury. The most striking result was that the oral MT treatment group (100 mg/kg) showed significantly decreased TNF-α expression compared with the radiation group, suggesting that oral MT impedes the up-regulation of TNF-α expression after radiation-induced SCI (Haddadi & Fardid, 2015). Activation of the nuclear factor-κB (NF-κB) signaling has also been implicated in the induction of inflammation and is considered one of the pathophysiological causes of the spinal cord inflammatory response following SCI (Mao, Wang, Qiao, & Wang, 2010). NF-κB further generates ROS, cyclooxygenase, and iNOS, which synergistically induce inflammation (Mao et al., 2010). Several lines of evidence suggest that MT inhibits the expression of NF-κB and attenuates the production of pro-inflammatory cytokines (Szczepanik, 2007). Recent research on MT suggested that this pineal hormone reduces secondary injury severity and neuronal death after SCI (Schiaveto-de-Souza, da Silva, Defino, & Del Bel, 2013). Another study conclusively showed that MT treatment effectively decreased inflammation and tissue injury in experimental SCI (Genovese et al., 2005). Overall, MT may exert neuroprotective effects on SCI by reducing inflammation and tissue damage after SCI (Fig. 2).

Effects of exogenous melatonin on autophagy

Autophagy plays a significant role in improving the neurological recovery process and enhances neurological function within a short time following acute SCI (Shen et al., 2017). Surprisingly, inhibition of autophagy markedly increased apoptosis in experimental SCI rats (Gao et al., 2016; Wang, Liu, Muharram, Wu, & Lin, 2014). In contrast, enhancing autophagy at the lesion site of the spinal cord significantly inhibited apoptosis (Wang et al., 2016), suggesting that increased levels of autophagy can reduce apoptosis, contribute to the neurological recovery process, and improve neurological function after SCI. A systematic review and network meta-analysis reported that MT improved locomotor recovery by inhibiting neuronal cell apoptosis in a rat model of SCI (Yang et al., 2016). Similarly, Shen et al. (2017) demonstrated that MT impeded neuronal cell apoptosis and encouraged locomotor recovery by activating the Wnt/β-catenin pathway following SCI. Previously, our group examined the endogenous and exogenous effects of MT on autophagic markers (beclin-1, LC3) in a contusion SCI rat model (Park et al., 2012). In that experiment, all groups were exposed to one of the following lighting conditions: 12/12 h light/dark (L/D) or 24/0 h constant light (LL). Western blot analysis showed that the transformation ratio of LC3-I to LC3-II protein was very low or undetectable in the normal control group (Park et al., 2012). Interestingly, the ratio was elevated after injury in a time-dependent manner, particularly in the SCI group under the L/D condition. At the site of the spinal cord lesion, the LC3-II protein level was increased at 3 days and peaked at 28 days post-SCI. In addition, no significant difference in beclin-1 expression was observed under the L/D condition, but its expression was significantly elevated under the LL condition. Surprisingly, exogenous MT treatment markedly decreased these effects under both L/D and LL conditions. Those findings suggest that autophagy-related cell death was increased in the spinal cord, and MT treatment accelerated motor recovery by down-regulation of LC3-II and beclin-1 (Park et al., 2012). These results corroborate with Kanno, Ozawa, Sekiguchi, and Itoi (2009), who also reported that the beclin-1 protein level was significantly increased at the lesion site after SCI. However, as mentioned above, up-regulation of autophagy inhibited apoptosis in the spinal cord, inducing neurological repair following SCI. A recent study

revealed that treatment with MT markedly increased the levels of autophagy-activated proteins, such as beclin-1 and LC3, but decreased the levels of apoptosis-activated proteins, such as caspase-3, caspase-9, and bax, in neurons after SCI (Li et al., 2019). Those findings indicate that MT can improve locomotor function by increasing autophagy as well as decreasing apoptosis after SCI in rats, probably via the PI3K/AKT/mTOR signaling pathway (Li et al., 2019). In summary, MT can increase autophagy, improve neuronal survival, and enhance locomotor function, while decreasing apoptosis in the spinal cord following SCI via the PI3K/AKT/mTOR signaling pathway. Alternatively, MT may improve neuronal survival by down-regulating autophagy-mediated apoptosis after SCI (Fig. 3). Further studies are required to clarify the differential effects of MT on autophagy in several experimental models of SCI.

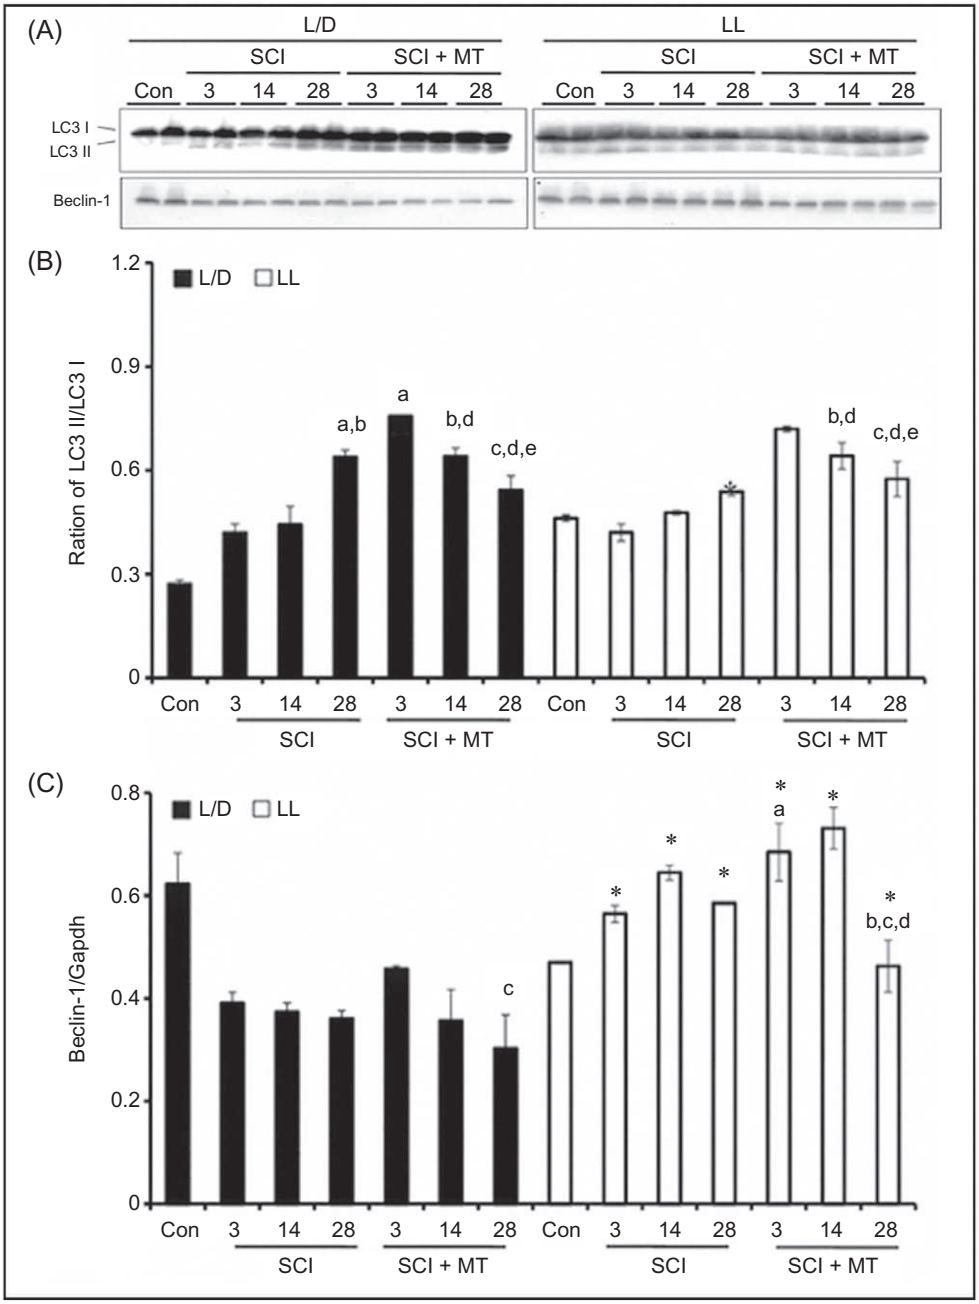

FIG. 3 Effects of exogenous melatonin on autophagy in the injured spinal cord after spinal cord injury. (A–C) Western blot analysis indicated that the autophagy-activating proteins (LC3-II and beclin-1) were decreased by melatonin treatment. *(Republished with permission from Park, S., Lee, S.-K., Park, K., Lee, Y., Hong, Y., Lee, S., Jeon, J.-C., Kim, J.-H., Lee, S.-R., Chang, K.-T., & Hong, Y. (2012). Beneficial effects of endogenous and exogenous melatonin on neural reconstruction and functional recovery in an animal model of spinal cord injury.* Journal of Pineal Research, 52, *107–119. Wiley. Permission conveyed through Copyright Clearance Center, Inc.)*

Combination treatment strategy for spinal cord injury

Although the single-intervention strategy has been effective in pre-clinical trials, the recovery process remains ineffective, and targeting a single barrier has been unsuccessful for improving functional recovery in cases of SCI in clinical trials. In contrast, combination treatment strategies that address diverse aspects of the pathology of SCI have been developed to achieve functional recovery after SCI (Hong et al., 2010; Lee et al., 2015). Most recent pre-clinical and clinical trials on functional recovery after SCI have focused on several combination treatment strategies, including (i) antioxidants plus exercise and (ii) glucocorticoids plus antioxidants (Hong et al., 2010). In this section, we discuss recent studies focusing on the beneficial effects of MT plus exercise on SCI.

Melatonin combined with exercise

Based on recent studies of SCI, the combination of MT and exercise was hypothesized to show synergistic effects, accelerating motor function recovery. As indicated previously, MT reduces LPO and increases the levels of several antioxidant enzymes after SCI (Erol et al., 2008; Erşahin et al., 2012; Liu et al., 2004), indicating that MT itself is a super antioxidant. On the other hand, exercise interventions can influence structural and functional changes in the cerebral cortex, spinal cord, and skeletal muscle, thereby promoting neural and muscular function after SCI. Exercise interventions can accelerate nerve regeneration with functional recovery (Doyle & Roberts, 2006; Park et al., 2015) and sustain the functionality of spinal cord neurons (Fu, Wang, Deng, & Li, 2016). Exercise can enhance neurological function following SCI but inadequate to improve motor function (Petrosyan et al., 2015). These limitations may be due to insufficient neurotrophic factor production by exercise training. In addition to exercise, therefore, several combination strategies have been investigated. Many studies have shown that antioxidants, such as MT, combined with exercise can considerably improve functional recovery following SCI and alleviate spasticity in rats compared with single interventions alone (Fig. 4). The benefit of this combination strategy is that MT can diminish the side-effects related to exercise, such as fatigue and impairment (Park, Park, Lee, Chang, & Hong, 2013). Recently, we reported synergistic effects of MT and exercise on neuronal repair and functional recovery in a contusion-induced SCI animal model (Park et al., 2010), suggesting excessive production of iNOS accelerates secondary damage to spinal tissue, which may be reversed by MT combined with exercise. The results of that study showed that MT combined with exercise markedly elevated hind limb movement, decreased iNOS expression, and increased the proportion of motor neurons in the ventral horn compared with exercise intervention alone (Park et al., 2010). Previously, we also reported synergistic effects of MT and exercise in a rodent SCI model, with notable behavioral enhancement, histological recovery, and elevated numbers of BrdU/nestin double-positive endogenous neural stem/progenitor cells (Lee et al., 2014). This study further demonstrated that MT and exercise intervention had a synergistic effect on nestin expression in the rostral perilesion site, suggesting that nestin may be associated with functional recovery. Using Golgi-Cox analysis, we showed that MT combined with exercise elevated dendritic spine density (Lee et al., 2014). Previously, our group also comprehensively reviewed the therapeutic effects of MT combined with exercise on SCI. In this review, we suggest that MT combined with exercise would not only enhance functional recovery but also alleviate the secondary tissue damage after SCI (Hong et al., 2010). Finally, we propose that future studies should explore the effects of MT and other antioxidants in combination with exercise on SCI recovery, representing a novel strategy for faster recovery after SCI (Hong et al., 2010). Finally, the combination of MT and exercise decreases the secondary injury related to SCI, and thus MT can reduce the side-effects associated with exercise.

Role of endogenous melatonin in spinal cord injury

Poor sleep quality is commonly observed in individuals with SCI, particularly those with tetraplegia, probably due to disruption of circadian rhythmicity (Fatima et al., 2016). SCI also causes circadian rhythm disruption such as dysregulated rhythms of body temperature, and inflammatory gene expression (Gaudet et al., 2018). Misalignment of circadian rhythmicity also alters endogenous MT secretion (Fatima et al., 2016), which further negatively affects the SCI recovery process. In contrast, the levels of endogenous MT were shown to increase under conditions of 24-h darkness, and the elevated endogenous MT levels subsequently showed anti-inflammatory and anti-oxidative effects in lesioned spinal cords, resulting in faster neural remodeling, such as axonal outgrowth, excitatory synapse formation, and oligodendrogenesis (Hong et al., 2019). To better understand, the roles of impaired circadian rhythmicity and its effects on sleep in SCI patients, (Verheggen et al., 2012) analyzed evening onset of MT patterns in patients with cervical (tetraplegia) or thoracic (paraplegia) SCI and revealed a higher prevalence of poor sleep quality in tetraplegia (83%) and paraplegia (75%) compared with able-bodied controls (20%). Additionally, they reported that even though the concentration of endogenous MT started to increase from the evening in both the control and paraplegia groups, this increase was completely absent in the tetraplegia

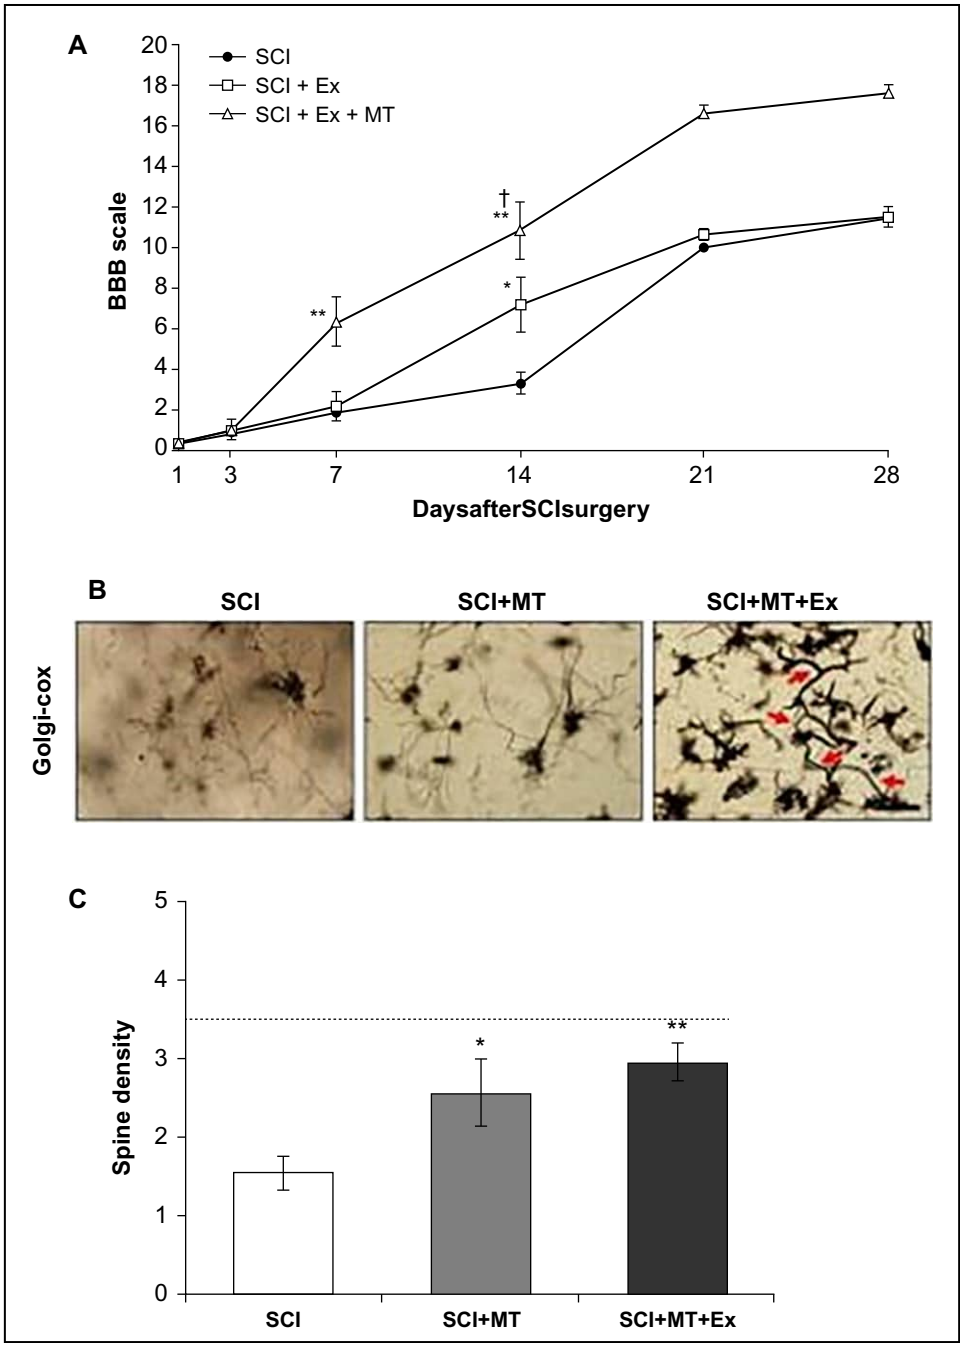

FIG. 4 Combined effects of melatonin and exercise on functional recovery after spinal cord injury. (A) The effects of melatonin combined with exercise on locomotor function in SCI. (B) Golgi-Cox staining indicated that melatonin and exercise promoted neurite outgrowth and production of new vessels *(red arrow)* after SCI. (C) After SCI, the combination of melatonin and exercise greatly increased dendritic spine density compared with melatonin alone. *(Republished with permission from Park, K., Lee, Y., Park, S., Lee, S., Hong, Y., Lee, S.K, & Hong, Y. group (Verheggen et al., 2012). Recently, Thøfner Hultén et al. (2018) also demonstrated that MT secretion was decreased to a greater extent in individuals with cervical SCI compared with thoracic SCI (Fig. 5). Patients with SCI were reported to show dysregulated circadian variation in thermoregulatory control (Jones et al., 2014). Elevation of MT during the evening was reported to be inversely correlated with core and skin temperature in able-bodied controls, particularly in paraplegic

Permission conveyed through Copyright Clearance Center, Inc.)*

individuals, while this correlation was absent in tetraplegic individuals during the same period (Jones et al., 2014). In clinical trials, individuals with tetraplegia were more likely to lose their nocturnal production of MT than were those with mild paralysis (Zeitzer, Ayas, Wu, Czeisler, & Brown, 2005), indicating that neurologically complete cervical SCI induces complete loss of nighttime MT production. In a study involving rats with SCI, Gezici, Karakaş, Ergün, and Gündüz (2010) reported that MT secretion began immediately after SCI but slowed substantially 2 to 6 h later. In an animal study, complete lesion of the lower cervical spinal cord was related to insufficient MT secretion; on the other hand, paraplegic rats with complete lesion of the upper thoracic spinal cord showed normal MT secretion (Gezici et al., 2010). The absence of nighttime MT secretion after cervical SCI may partially explain the observed sleep disturbance. These findings raise the possibility that MT replacement therapy may improve sleep in patients with tetraplegia (Scheer et al., 2006). The endogenous MT levels in individuals with complete cervical SCI and healthy controls are illustrated in Table 1.

Clinical application of melatonin in spinal cord injury

Several randomized controlled trials (RCTs) have been conducted to assess the effects of exogenous MT treatment on endogenous MT levels and sleep outcomes in individuals with cervical SCI. Most RCTs showed that endogenous MT levels generally increase with MT supplementation, although there were no impacts on subjective or objective parameters of sleep (Fatima et al., 2016; Kostovski et al., 2015; Spong et al., 2014; Spong, Kennedy, Brown, Armstrong, & Berlowitz, 2013; Zeitzer, Ku, Ota, & Kiratli, 2014). Generally, those trials involved MT supplementation long after the initial injury, with most of the studies conducted at least 16 years after the presenting injury. In this regard, it is hypothesized that MT administration shortly after the initial injury may improve sleep quality. However, Kostovski et al. (2017) reported that the fluctuation of MT concentration alters the expression of several clock genes in individuals with tetraplegia, while exogenous MT treatment may align the expression of these clock genes. Previous studies evaluated the clinical effects of exogenous MT only on sleep in patients with complete cervical SCI. There have been no reports regarding the effects of exogenous MT on neurological recovery or pain scores after complete cervical SCI, and therefore future studies are urgently required. Furthermore, characterization of endogenous MT levels during different phases of SCI is also important to optimize the timing of MT supplementation, as previous trials were performed several years after the initial injury, when the window of beneficial clinical effects may have been missed.

Conclusion

Experimental studies have indicated that exogenous MT may restore neurological function and have neuroprotective effects on SCI. Several cellular and molecular mechanisms, such as reduction of oxidative stress, attenuation of iNOS

TABLE 1 Endogenous melatonin levels in individuals with cervical spinal cord injury.

and pro-inflammatory cytokines, and regulation of autophagy, may be involved in neuroprotection on SCI. The beneficial effects of MT have been shown to be greater when combined with exercise, particularly for neural regeneration and functional recovery after SCI. However, additional studies are needed to determine the proper timing and intensity of MT and exercise for use in clinical practice. Future studies should also explore the effects of MT and other antioxidants and/or traditional anti-inflammatory drugs in combination with exercise on recovery after SCI, which would represent a novel strategy for faster recovery after SCI. Both pre-clinical and clinical trials have shown that endogenous MT production and release are altered and play significant roles in the SCI recovery process. Therefore, further studies are also needed to understand the cellular and molecular mechanisms underlying the pathophysiological effects of altered endogenous MT levels and to identify novel targets for the development of clinical therapies that can be used in SCI patients.

Applications to other areas of neuroscience

The pathophysiological mechanisms of SCI are similar to those of various neuronal disorders, such as ischemic stroke and traumatic brain injury. For example, excessive ROS production is a significant contributor to secondary injury in stroke. Similarly, most pre-clinical research in animal models has also demonstrated that increased production of ROS and consequential development of oxidative stress are crucial pathological events in SCI, which lead to neurological deficits. The considerable level of ROS further stimulates production of abundant pro-inflammatory molecules, including IL-1α, -1β, and TNF-α, which further provoke both SCI and stroke pathology. Moreover, in SCI, the activation of autophagy in the

injured spinal cord may be a double-edged sword for neuronal survival similar to ischemic stroke. As similar pathophysiological mechanisms are involved in both cases, MT, which shows neuroprotective and neuroregenerative effects in SCI, may be helpful for neural regeneration and functional recovery after ischemic stroke. As for SCI, the pathophysiological process of stroke is multifactorial, and therefore combination treatment strategies that address diverse aspects of stroke pathology are required. In this chapter, we highlighted that the combination of MT and exercise exerts synergistic effects to reduce the secondary injury pathologies related to SCI. This combination strategy may also be more effective and promote faster recovery after stroke.

Mini-dictionary of terms

- **Autophagic flux:** A process to quantify the rate of autophagic degradation.
- **Circadian misalignment:** An incorrect arrangement of sleep/wake pattern.
- **Paraplegia:** A state of sensory and motor function loss following injury to the thoracic region of the spinal cord.
- **Secondary injury:** Catastrophic molecular events in cells and tissues, beginning immediately after the primary insult and continuing for hours to weeks, resulting in further damage to cells and tissues.
- **Tetraplegia:** A state of sensory and motor function loss following injury to the cervical region of the spinal cord.

Key facts

Key facts of melatonin and exercise combination strategy for spinal cord injury

- Melatonin and exercise exert synergistic effects on neuronal repair and functional recovery after spinal cord injury.
- Melatonin can diminish the side effects of exercise.
- Melatonin combined with exercise can result in faster motor recovery compared with exercise intervention alone.
- Melatonin combined with exercise intervention triggers nestin expression.
- In spinal cord injury, nestin may be associated with the functional recovery process.

Key facts of endogenous melatonin levels after spinal cord injury

- The secretion of melatonin appears to be decreased to a greater extent in individuals with cervical than thoracic spinal cord lesions.
- The concentration of endogenous melatonin started increasing from the evening in both the able-bodied and paraplegia groups, whereas this increase was completely absent in the tetraplegia group.
- The evening increase in melatonin concentration was inversely correlated with core body temperature in the able-bodied and paraplegia groups, but this correlation was completely absent in tetraplegic individuals.
- The absence of nighttime melatonin secretion after cervical spinal cord injury partially explains the sleep disturbance.
- In clinical trials, endogenous melatonin levels generally increase with exogenous melatonin supplementation.
- Elevated endogenous melatonin causes faster neural remodeling, such as axonal outgrowth and formation of excitatory synapses, after experimental spinal cord injury.

Summary points

- Exogenous melatonin treatment notably decreased LPO and restored the levels of antioxidant enzymes, including GSH and SOD.
- Melatonin treatment effectively decreased the levels of pro-inflammatory molecules, such as TNF-α, IL-1β, and iNOS.
- Melatonin can decrease apoptosis by increase autophagy via the PI3K/AKT/mTOR signaling pathway.
- The combination of melatonin and exercise resulted in faster functional recovery.
- The endogenous melatonin secretion pattern was significantly altered following cervical spinal cord injury.

AGREE	Appraisal of Guidelines, Research and Evaluation
HIIT	high-intensity interval training
MIT	moderate-intensity continuous training
NSCISC	National Spinal Cord Injury Statistical Center
SCI	spinal cord injury
SIT	sprint interval training
T2D	type 2 diabetes
VO_2 max	maximal oxygen consumption

Introduction

This chapter summarizes the public health issue of physical inactivity (i.e., lack of participation in health-enhancing exercise behavior) among people with spinal cord injury (SCI). The purpose of this chapter is to provide the reader with an understanding of the importance of exercise and potentially advantageous types of exercise for people with SCI, with a particular focus on high-intensity interval training (HIIT). The chapter is broken into four sections. The first section will present current incidence and prevalence data as well as healthcare burden statistics on individuals with SCI. The second section highlights cardiometabolic comorbidities associated with SCI, low levels of exercise, and difficulties (i.e., barriers) associated with participation. The third section summarizes benefits, guidelines, and strategies to promote exercise participation. The fourth section highlights recent findings on HIIT interventions among people with SCI and developing research in this area.

Section 1: Background and overview

Incidence and prevalence

The National Spinal Cord Injury Statistical Center (NSCISC) estimates 291,000 people are living with an SCI in the United States with 17,730 new cases each year, or 54 per million (National Spinal Cord Injury Statistical Center, 2019). Other studies have found similar incidence rates, ranging from 52 to 56.4 per million (Jain et al., 2015); however, due to varying methodologies, other reports include prevalence estimates of 1.5 million to 2.6 million (GBD 2016 Traumatic Brain Injury and Spinal Cord Injury Collaborators, 2016). For decades, the typical person acquiring SCI was 29; however, that has increased to 43, likely due to an increase in the etiology of falls among an aging population. People with newly acquired SCI are typically male (78%) and white (59.5%) with leading causes of injury vehicle crashes (39.3%) and falls (31.8%). The majority of injuries are incomplete, either tetraplegia (47.6%) or paraplegia (19.9%) followed by complete paraplegia (19.6%) and complete tetraplegia (12.3%).

Diagnosis and Treatment of Spinal Cord Injury. https://doi.org/10.1016/B978-0-12-822498-4.00030-0

Healthcare and economic burden

Healthcare burden is largely dependent upon the degree of severity of the SCI with hospitalizations in the first year of injury, which includes the bulk of the direct cost estimated at 1.7 billion in the United States (Mahabaleshwarkar & Khanna, 2014). For example, an individual with tetraplegia and vent-dependent has an average healthcare expenditure over 1.2 million dollars in the first year after injury with almost $200,000 in subsequent years, whereas someone with paraplegia cost estimates include $550,381 for the first year and $72,909 in subsequent years (National Spinal Cord Injury Statistical Center, 2019). The first year after following injury is the costliest and the most critical to the life of the person with SCI, as life expectancy increases significantly after living past the first year of injury. For individuals injured at 20 years old, estimated life loss is 7 years among individuals with paraplegia and 48 years of life loss among individuals with higher injury levels and vent dependency. In addition to direct cost and life loss, indirect cost, such as loss of earnings and productivity, is estimated at $76,237 per year.

Depending on the level of injury and personal response, many individuals do not return to full-time work or even part-time work. Data from NSCISC show 66% of individuals working at time of injury with only 17% working 1 year out and 23% working 10 years after injury. Lastly, length of stay for rehabilitation after sustaining an SCI has been reduced from 98 to 34 days over the last 50 years (The 2018 Annual Statistical Report for The Spinal Cord Injury Model Systems, 2018). Post-acute rehabilitation offers people with SCI the benefit of individualized, intensive training before returning home. However, shorter length of stay and lack of intensive programming for the home has been linked to higher incidence of rehospitalization due to secondary health conditions, as well as increased discharge to institutional settings rather than the home, all of which drive healthcare cost (Eastwood, Hagglund, Ragnarsson, Gordon, & Marino, 1999; Rimmer, 2012; Tschoepe, Benfield, Mercer, & Posey, 2019).

Section 2: Cardiometabolic comorbidities associated with SCI

This section will present cardiometabolic comorbidities associated with SCI. There is greater prevalence of these comorbidities due to deconditioning and the myriad of barriers to exercise for this population. Similar to other disability groups, people with SCI encounter three different categories of conditions. This includes the associated conditions, such as paralysis and its impacts motor functioning, sensation, and bodily processes (e.g., bladder functioning); secondary health conditions, such as neuropathic pain, urinary tract infections, pressure ulcers, and social isolation; and chronic conditions (i.e., heart disease, obesity).

Associated risk factors

People with SCI have reduced physical functioning due to loss of motor functioning and loss of muscle mass, which result in deleterious cardiometabolic effects. People with SCI have high rates of secondary health conditions, which are defined by the Institute of Medicine as preventable conditions secondary to the associated condition. These secondary conditions (e.g., pain, pressure ulcer) lead to a downward spiral in health and function for people with SCI and in the aggregate, can impose substantial limitations in rates of participation including employment, social engagement, and performing activities of daily living (Ehde et al., 2003; Ginis et al., 2010; Latimer, Martin Ginis, Craven, & Hicks, 2006; Martin Ginis & Hicks, 2005; Rajan, McNeely, Warms, & Goldstein, 2008; Tian et al., 2013; Turner, Cardenas, Warms, & McClellan, 2001). The NCISC reported in 2018 that within the first year of sustaining an SCI, 36.5% of patients are re-hospitalized due to infections associated with the urinary, respiratory, or integumentary system, with an average length of hospitalization of 19 days (The 2018 Annual Statistical Report for The Spinal Cord Injury Model Systems, 2018). Additionally, Skelton, Hoffman, Reyes, and Burns (2015) reported that within the first year of sustaining an SCI, 57% used emergency room care. Following rehabilitation, health trajectories in people with SCI are impacted by the onset and course of these secondary conditions and their "additive" effect on changes in health and function (Adriaansen et al., 2016). Some of the highest rates of physiological secondary conditions in people with SCI include excess weight gain (i.e., obesity) (Gorgey & Gater, 2007; Laughton, Buchholz, Martin Ginis, & Goy, 2009; Rajan et al., 2008; Tian et al., 2013), extremely low fitness levels (Ginis et al., 2010; Latimer et al., 2006; Martin Ginis & Hicks, 2005), and pain (neuropathic and musculoskeletal) (Ehde et al., 2003; Turner et al., 2001; Fig. 1).

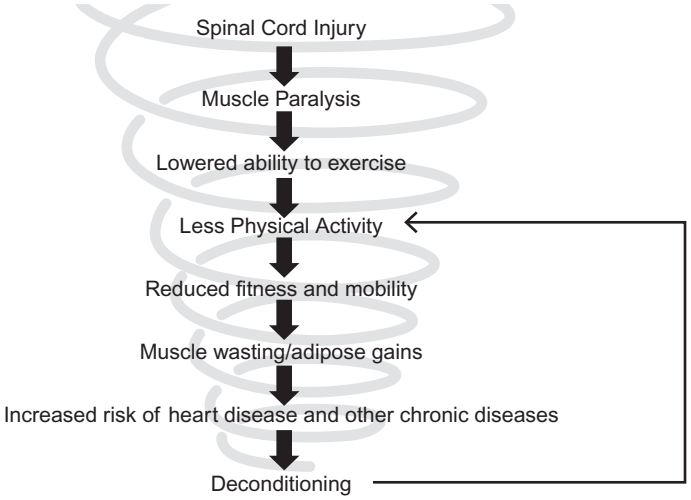

FIG. 1 Downward spiral of deconditioning among people with SCI.

Health disparities, barriers, and SCI

People with SCI have higher rates of health disparities, which includes lower levels of physical activity. Data show that around half of people with SCI obtain little to no aerobic physical activity, which has resulted in people with SCI at three times more likely to have chronic conditions, such as heart disease, obesity, and stroke than the general population (Carroll et al., 2014; Ginis et al., 2010). This is largely due to the reduced physical functioning and sedentary lifestyles acquired by many individuals with SCI due to the issues of deconditioning and secondary conditions discussed in the above section (Galea, 2012; Rimmer, Schiller, & Chen, 2012). This is also related to the low rates of employment previously mentioned, as well as other lower quality of life indicators among people with SCI. There is an extreme challenge faced by people with SCI to lead an active and healthy lifestyle because of muscle loss, reduced motor functioning, and health, environmental, and logistical barriers (Galea, 2012; Martin Ginis, Ma, Latimer-Cheung, & Rimmer, 2016). Deconditioning is only one aspect of a plethora of exercise barriers that span each level of the social ecological model for people with SCI. Many systematic reviews have highlighted the issue of barriers to exercise among people with SCI (Martin Ginis et al., 2016). At the intrapersonal level, people with SCI have low levels of self-efficacy, fear of injuring themselves, and experience an increase in musculoskeletal pain, as well as the addition of neuropathic pain, due to the SCI. On the interpersonal level, there is a lack of social support for individuals with SCI resulting in cases of learned helplessness, which is detrimental to gaining independence. Next, there is a lack of awareness and knowledge about supporting exercise behavior among people with SCI at the organizational level and lack of accessible fitness centers, exercise programs, and equipment at the community level. Lastly, the largest barrier to exercise has been transportation with many dependent upon public transportation.

Section 3: SCI exercise benefits, guidelines, and participation

This section will cover the current state-of-the-science regarding exercise benefits and guidelines for SCI. To date, there are three topic areas in SCI exercise research that are receiving substantial attention: (1) exercise benefits, (2) exercise guidelines, and (3) participation issues. The first subsection, exercise benefits, will summarize the anticipated benefits that people with SCI can obtain from exercise participation. The second subsection will briefly overview issues participation in exercise research. The third subsection will summarize the latest guidelines or recommendations to exercise for people with SCI.

Exercise benefits

Exercise research for SCI is a relatively new area of research inquiry that emerged around the 1980s. Because of this, there is limited high-level evidence that confirms precise physiological benefits of exercise among this population.

Unfortunately, the relatively small prevalence of SCI has made it difficult for researchers to confirm the benefits of exercise in SCI within large high-quality trials, such as randomized controlled trials. This lack of trials has resulted in few systematic reviews for SCI compared with other disability groups (e.g., stroke and multiple sclerosis) and, ultimately, no meta-analyses. Therefore, while the benefits for SCI are likely similar to those observed in the general population, there is a lack of research evidence supporting interventions that can lead to actual benefits in SCI. This makes it difficult for clinicians to prescribe exercise and improve participation. Nevertheless, we hereby present the latest high-quality evidence of benefits in SCI as of the time of this publication.

In 2017, a high-quality systematic review of exercise studies for people SCI reported that exercise could improve fitness cardiometabolic health (Ginis et al., 2018; van der Scheer et al., 2017). The review included a total of 211 studies where exercise interventions were delivered. The review included non-randomized studies (non-randomized trials, case studies, etc.) in addition to randomized studies, which means that we should interpret not only their findings but also the confidence they had in their findings. There were insufficient high-quality studies that included people with acute SCI ($\leq$12 months post-injury). Thus, the findings were presented only for people with chronic SC (189/211 studies). The key findings are presented below:

Benefits summary: (Ginis et al., 2018; van der Scheer et al., 2017)

- Low to moderate confidence evidence demonstrates that exercising 3 to 5 times per week at a moderate to vigorous intensity can improve cardiorespiratory fitness, muscular strength and metabolic health (body composition and cardiovascular risk factors).
- Different doses of exercise result in different health benefits.
- Doses of lower training durations and frequencies can improve fitness (i.e., cardiorespiratory fitness and muscular strength/power).
- Whereas doses with higher training durations and frequencies appear to be necessary to result in cardiometabolic health improvements.

These findings had important implications and informed the development of the latest SCI exercise guidelines.

Of note, the published studies primarily base their evidence off of short-term clinical studies. In other words, the studies are conducted in highly controlled laboratory or clinical settings, as opposed to real-world changes in the lifestyle of the person with SCI after the study. A scoping review examined whether exercise benefits could be sustained after completing the formal intervention of an intervention for adults with disabilities (Lai et al., 2019). The report identified that, from exercise trials published from 2006 to 2016, only one study for SCI found a sustained benefit toward a health outcome that lasted throughout a follow-up period (a period after completing a formal intervention component). Consequently, there is a need to identify programs that not only improve health and function in the short term for SCI, but also demonstrate long-term benefits, which will ultimately require strategies that promote long-term participation.

Exercise guidelines

Given the infancy of the field, exercise guidelines or recommendations designed specifically for SCI are quite new and still evolving. The latest and most widely acknowledged exercise guidelines were created in 2017 by a large international team of highly respected disability-exercise scientists, led by Dr. Kathleen Martin Ginis the University of British Columbia, Canada and Victoria Goosey-Tolfrey at Loughborough University, United Kingdom (Ginis et al., 2018; van der Scheer et al., 2017). The guidelines were split into two different categories, fitness benefits and cardiometabolic health, as stated below:

Guidelines summary: (Ginis et al., 2018; van der Scheer et al., 2017)

- Aerobic exercise should be performed 2 to 3 sessions per week at a moderate to vigorous intensity for 20 to 40 min (at minimum, 20 min).
- Strength exercise should be performed 2 to 3 times per week and each session should include 3 sets of 10 repetitions for large muscle groups (weight should be set at 50% to 80% of the person's maximum weight; at minimum 3 sets should be performed in a week).

When prescribing these guidelines to people with SCI, there are a few important concepts to note. The duration component for aerobic exercise necessary to anticipate health benefits is, at minimum, 20 min. If improving health is the primary goal, people with SCI should aim to exceed the SCI guidelines, particularly since guidelines for SCI are lower than those for the general adult population. The US Department of Health and Human Services recommends the general adult population and adults with disabilities should aim to achieve at least 150 to 300 min of moderate-intensity aerobic exercise per week; or 75

to 150 min of vigorous intensity aerobic exercise (US Department of Health and Human Services Physical Activity Guidelines for Americans, 2018). The collective evidence suggests that the SCI exercise guidelines should be considered as a minimum recommendation or a starting point for exercise promotion. The long-term goal should be to progress toward higher volumes (frequency of exercise sessions per week and session durations) of exercise overtime. As a final note, there will certainly be many people with SCI who will have difficulty achieving or may never achieve the SCI guidelines (barriers discussed in the last subsection). Although achieving the guidelines is an important target for exercise prescription, know that some exercise is always better than none: gains can be made from even low levels of exercise participation, particularly in people who are physically deconditioned or new to exercise.

Exercise participation

Although there is an encouraging amount of literature demonstrating benefits, ultimately, published studies have not demonstrated much success with identifying programs that can increase exercise participation. Specifically, there have been no evidence-based programs successful at maintaining exercise participation over a long term (Lai et al., 2018) and, most importantly, there is substantial difficulty with getting people with SCI enrolled into an exercise intervention. A review study (Lai et al., 2018) found the mean sample size of randomized controlled trials published between the years 2006 to 2016 was 25 people; 14 people per study group when they were randomized to a treatment group and control group. This means exercise interventions may have poor generalizability (i.e., findings may not be able to be projected to the population as a whole), and we must be careful when interpreting study findings. This limitation is currently the largest factor that impedes the growth of exercise research in SCI.

To address this issue, we would urge researchers to use theory-based strategies to enroll people with SCI into exercise interventions or programs. Behavioral change strategies that are framed upon theories (e.g., social cognitive theory) have been found to be successful for promoting physical activity throughout an intervention for people with SCI, albeit for short-to-mid terms (Ma & Martin Ginis, 2018). Conceivably, theory-based strategies should also frame how we enroll people with SCI into exercise interventions. Our team conducted a qualitative investigation that generated a theory for enhancing the likelihood of success with enrollment (Lai et al., 2020). The theory posits that wheelchair users with SCI ($n = 33$) conceive three core concerns with enrolling into an exercise intervention: (1) they first assess their capability to participate in the program due to scheduling, transportation, and secondary health conditions; (2) they mentally balance anticipated benefits versus the difficulty of starting the program; and (3) they assess the desirability of the program characteristics based upon their needs and preferences. Successful recruitment will depend on a recruiters ability to address these three concerns while presenting time-efficient, accessible, and desirable programs (Lai et al., 2020).

Section 4: Health benefits of high-intensity interval training

The primary cited reason for not participating in regular exercise in non-disabled individuals is perceived "lack of time" (Lai et al., 2021; Trost, Owen, Bauman, Sallis, & Brown, 2002). With this in mind, individuals with SCI face even greater challenges as they have few, if any options to participate in physical activity. Three of the most frequently reported barriers to participation, are structural (accessibility to exercise facilities, exercise equipment), time-related (getting dressed/undressed, unreliable transportation services), and lack of knowledgeable exercise personnel (Scelza, Kalpakjian, Zemper, & Tate, 2005). Thus, it is imperative that novel exercise strategies are identified to address these barriers in individuals with SCI.

High-intensity interval training in able-bodied individuals

One mode of training that may overcome some of these barriers and provide similar cardiometabolic health benefits is low-volume high-intensity interval training (HIIT). HIIT can be performed many different ways, but usually consists of brief intervals of higher intensity exercise performed between (~80%–200% of VO_2 max) separated by rest intervals of lower intensity exercise or complete rest (Gillen et al., 2016; MacInnis & Gibala, 2016). Furthermore, interval training can be broken down to HIIT, which consists of repeated bouts of exercise performed at workloads between the ventilatory threshold and VO_2 max, or sprint interval training (SIT), which is performed at workloads greater than VO_2 max (Buchheit & Laursen, 2013; Gibala, Gillen, & Percival, 2014). At this point, there are insufficient data to support the idea that individuals with SCI are able to perform SIT, which requires maximal or supramaximal efforts for the duration of the interval. Thus, for simplicity, we will refer to both of these terms as HIIT when referring to the effects on individuals with SCI throughout this chapter. A growing body of evidence in non-disabled individuals, from our group (Fisher et al., 2015)

and others (Burgomaster et al., 2008; Martins et al., 2015; Richards et al., 2010; Whyte, Gill, & Cathcart, 2010) has demonstrated the potential for low-volume high-intensity interval training (HIIT) to provide comparable or superior improvements in cardiometabolic health outcomes compared to continuous moderate-intensity training (MIT) requiring 60% to 80% greater time commitment. For example, we recently found similar improvements in % fat, blood lipids, and insulin sensitivity in obese males following 6 weeks of training despite HIIT only requiring 20% of the total time commitment as MIT. Importantly, this mode of exercise has been shown to be well tolerated in many different clinical populations, including type 2 diabetes (T2D) (Boudou, Sobngwi, Mauvais-Jarvis, Vexiau, & Gautier, 2003; Little et al., 2011), overweight/obesity (Fisher et al., 2015; Gillen, Percival, Ludzki, Tarnopolsky, & Gibala, 2013; Whyte et al., 2010), cardiovascular disease (Warburton et al., 2005), and metabolic syndrome (Tjønna et al., 2008). Thus, HIIT appears to be a mode of exercise that is well-tolerated, requires minimal time commitment, and provides many of the same cardiometabolic health benefits as MIT in non-disabled individuals.

High-intensity interval training in individuals with spinal cord injury

Exercise guidelines for non-disabled individuals have been developed based on modes of exercise that require weight bearing activities such as running and walking or lower-body exercise such as cycling. This is uniquely different than exercise programs in individuals with SCI, in which upper body exercise training (arm crank cycling, wheelchair movement, and upper body resistance training) is the primary mode used and consists of upper body muscle mass. When SCI occurs, there is a decline in aerobic capacity, onset of skeletal muscle atrophy, increases in body fat, and impaired cardiometabolic health. Thus, this rapid deconditioning greatly enhances risk of cardiovascular and metabolic diseases then able bodied populations (Bauman & Spungen, 2001). Furthermore, while there have been few long-term studies assessing the benefits of exercise on individuals with SCI a recent study showed improvements in VO_2 max and muscular strength compared to no-exercise controls. However, there were no changes in body composition, blood lipids, or blood glucose and insulin following 16 weeks of combined aerobic and resistance training exercise performed twice a week (Totosy de Zepetnek, Pelletier, Hicks, & MacDonald, 2015), suggesting the potential need for greater volume or intensity to modify cardiometabolic risk factors. Thus, HIIT is an attractive form of training to address these potential limitations following lower volume or moderate-intensity exercise. To date, there have been few well-powered studies assessing the potential benefits for improving cardiometabolic health in individuals with SCI. Overall, studies (Brurok, Helgerud, Karlsen, Leivseth, & Hoff, 2011; Harnish, Daniels, & Caruso, 2017; Hasnan, Engkasan, Husain, & Davis, 2013; Tordi et al., 2001) not including a MIT exercise comparison group showed increases in VO_2 peak and peak power output, and have also shown improved stroke volume (Brurok et al., 2011), and decrease % body fat (Harnish et al., 2017). Whereas studies that have compared HIIT to MIT training groups have shown similar improvements in VO_2 peak (de Groot, Hjeltnes, Heijboer, Stal, & Birkeland, 2003; Graham et al., 2019), insulin sensitivity (de Groot et al., 2003; Graham et al., 2019), and peak power output (de Groot et al., 2003; Mcleod, Diana, & Hicks, 2020). Thus, it appears that HIIT can improve some components of cardiometabolic health, similar to that seen following MIT exercise; however, it remains difficult to compare results between studies due to a lack of standardized exercise guidelines when implementing HIIT.

While there is much work needed to draw conclusions of the efficacy of HIIT for improving health in individuals with SCI, several recent studies have shown greater exercise enjoyment (Astorino & Thum, 2018; Gauthier, Brosseau, Hicks, & Gagnon, 2018) following HIIT compared to MIT (15, 20). Furthermore, HIIT studies to date have reported minimal (Astorino & Thum, 2018; Brurok et al., 2011; Gauthier et al., 2018) or no adverse responses (Graham et al., 2019; Mcleod et al., 2020) to HIIT. Therefore, HIIT appears to be a feasible and tolerable form of training in individuals with SCI. Future well powered and long-term studies are needed to determine if HIIT is a more attractive form of training that can address the major barriers (lack of time, enjoyment, and access to facilities) to exercise participation and exercise adherence in individuals with SCI, and lead to long-term improvements in cardiometabolic health.

Telehealth strategies to promote exercise adherence to high-intensity interval training

Participation in exercise remains low in individuals with SCI (50% sedentary) (Ginis et al., 2010). Adherence to exercise treatments in disabled individuals is often reported to be less than 50% (Forkan et al., 2006; Kolt & McEvoy, 2003; McLean, Klaber Moffett, Sharp, & Gardiner, 2013). In addition to low adherence rates, the majority of SCI exercise training studies to date have had small sample sizes (mean = 14) and were often underpowered to determine primary treatment effects (Lai, Young, Bickel, Motl, & Rimmer, 2017). Thus, it is critical to identify novel strategies and tools that can increase exercise participation and improve rates of adherence in SCI. Recent advances in technology, such as smartphones and internet streaming, have been used to deliver health care services to individuals at home. Thus, with emerging

technology it is possible for the implementation of home-based telehealth exercise, which may enable us to overcome many of the reported barriers, such as transportation, accessibility to exercise facilities, and access to knowledgeable exercise personnel (Scelza et al., 2005), in individuals with SCI.

To date, there have been a few pilot studies testing the efficacy of various telehealth exercise interventions (telephone, video, and web-based approaches) in individuals with SCI (Arbour-Nicitopoulos, Tomasone, Latimer-Cheung, & Martin Ginis, 2014; Coulter et al., 2017; Lai, Rimmer, Barstow, Jovanov, & Bickel, 2016; Sweet, Rocchi, Arbour-Nicitopoulos, Kairy, & Fillion, 2017). Telephone-based exercise counseling has been shown to increase exercise participation in adults with SCI from 35% at baseline to 52% after 6 months (Arbour-Nicitopoulos et al., 2014). A recent pilot study by our group assessed an aerobic exercise training program delivered remotely using an upper body ergometer, tablet, physiological monitor, and custom application that delivered video feed to a remote trainer and monitored and recorded exercise data in real time (Lai et al., 2016). This approach resulted in completion of all 24 sessions during the 8 weeks of training and 100% adherence. Another advantage is that technology-based programs might also increase the likelihood that outcomes are maintained after an exercise trial is completed. In a recent review, we observed that technology-driven interventions sustained 56% of all outcomes measured at follow-up, which was higher than all other exercise modalities and the mean of all studies (32%) (Lai et al., 2018). Collectively, these studies demonstrate that home-based telehealth exercise training can be implemented safely and allows individuals and investigators to overcome many of the common barriers to exercise participation and research in SCI. Given the potent health improvements observed following low-volume HIIT and the ability to implement a home-based telehealth exercise approach, HIIT delivered via telehealth may be an optimal exercise training program that improves cardiometabolic health, requires little time, and reduces environmental barriers that typically prevent exercise in SCI. Current research by our group will assess the potential for home-based telehealth HIIT exercise for improving cardiometabolic health in individuals with SCI. We anticipate greater adherence to exercise and significant health improvements as it has been shown that one-on-one training and attention from the trainers are key factors that will make HIIT enjoyable, as it has been shown that working with personal trainers significantly increase adherence to exercise (Tulloch et al., 2013).

Applications to other areas of neuroscience

In this chapter, we have reviewed the impact that spinal cord injury has on the risk and prevalence of developing chronic cardiometabolic diseases. We discuss the benefits that exercise training can have for improving or preventing these adverse health outcomes, and highlight the potential role of high-intensity interval training as a mode of exercise that may lead to greater health benefits and adherence in individuals with spinal cord injury. HIIT has gained traction in recent years as it has shown to provide many similar or superior health benefits as prolonged moderate-intensity exercise training despite requiring a significantly reduction in overall time commitment. It remains to be determined if this mode of exercise will provide similar results in SCI as seen in able-bodied individuals, however a number of studies in other neurological diseases have shown promising results. HIIT was shown to be a feasible form of exercise training that improved cardiovascular fitness, vascular hemodynamics, and cognitive function in individuals with Parkinson's disease (Fernandes et al., 2020; Harvey et al., 2019). HIIT has also been shown to reduce pain, fatigue, stiffness, and inflammation in patients with axial spondyloarthritis (Sveaas et al., 2020). The assessment of HIIT in patients with neurological diseases is relatively new, thus future well controlled and statistically powered studies will better determine the long-term health benefits in individuals with SCI and other neurological conditions.

Mini-dictionary of terms

Spinal cord injury: Traumatic damage to the spinal cord causing a certain degree of paralysis and loss of neurological function.
Paraplegia: Paralysis of the lower limbs.
Tetraplegia: Paralysis of all four limbs.
Healthcare burden: The direct (e.g., hospital stay) and indirect cost (e.g., loss of wages) associated with care for the injury and the lasting effects.
Secondary health conditions: Conditions associated with a disability, either directly or indirectly, and preventable or manageable through healthy behavior, such as exercise.
Psychosocial: The intersection of an individual's psychology and their interaction with their social environment.
Sample size: The number of people enrolled in a research study.

Systematic review: A review that takes a rigorous approach to aggregating and summarizing the effects of published research studies.
Health disparity: Differences in health due to unequal access or resources.
High-intensity interval training: A mode of exercise consisting of brief intervals of higher intensity exercise separated by rest intervals of lower intensity exercise or complete rest.
Moderate-intensity continuous training: A mode of exercise training that involves steady state continuous exercise without rest intervals.
Cardiometabolic health: Risk factors, such as dyslipidemia, elevated blood pressure, impaired glucose intolerance, obesity, reduced cardiovascular fitness, that increase risk of developing diabetes, heart disease, or stroke.

Key facts of SCI and exercise

- Individuals with SCI have reduced physical functioning due to loss of motor function and loss of muscle mass.
- When SCI occurs there is a decline in aerobic capacity, onset of skeletal muscle atrophy, increases in body fat, and impaired cardiometabolic health.
- The primary cited reason for not participating in regular exercise in non-disabled individuals is perceived "lack of time."
- HIIT is a form of training that consists of brief intervals of higher intensity exercise performed between (~80%–200% of VO_2 max) separated by rest intervals of lower intensity exercise or complete rest.
- HIIT appears to be a mode of exercise that is well-tolerated, requires minimal time commitment, and provides many of the same cardiometabolic health benefits as MIT despite requiring significantly less time.

Summary points

- High rates of secondary medical conditions among individuals with SCI include pressure sores, urinary tract infections, and pain.
- Individuals with SCI have reported lower levels of physical activity compared to individuals without a disability.
- Barriers to exercise for people with SCI include unreliable transportation, inaccessible facilities, and lack of knowledge among exercise trainers.
- Exercise guidelines for SCI recommend a minimum of 20 min of aerobic activity 2 to 3 times per week and strength exercise performed 2 to 3 times.
- More needs to be done in creating effective and enjoyable HIIT exercise interventions for individuals with SCI.
- Telehealth could be used to circumvent the majority of barriers to exercise and provide an enjoyable experience with exercise.

Chapter 31

Stem cells and chronic spinal cord injury: Overview

Leonardino A. Digma, Pavan S. Upadhyayula, Joel R. Martin, and Joseph D. Ciacci
Department of Neurological Surgery, University of California San Diego, San Diego, CA, United States

Abbreviations

ALS	amyotrophic lateral sclerosis
BDNF	brain-derived neurotrophic factor
CNS	central nervous system
DNA	deoxyribonucleic acid
EMG	electromyography
ESC	embryonic stem cell
GABA	gaba-aminobutyric acid
iPSC	induced-pluripotent stem cell
ISNCSCI	International standards for neurological classification of spinal cord injury
MSC	mesenchymal stem cell
ROS	reactive oxygen species
SCI	spinal cord injury

Introduction

Spinal cord injury (SCI) is a devastating condition that is associated with a poor prognosis and long-lasting disability. Globally, SCI has an incidence of 8 to 246 per million and a prevalence of 236 to 1298 per million (Furlan et al., 2013). The lifetime cost for healthcare and living expenses that are attributable to SCI ranges from $1 to $4 million (*The Journal of Spinal Cord Medicine*, 2014). The destruction and demyelination of neurons that occurs in SCI leads acutely to quadriplegia, paraplegia, quadriparesis, and paraparesis, depending on the degree and location of injury. Furthermore, damage to neurons, glia, and vasculature also triggers a downstream sequence of events mediated primarily by inflammatory cells and cytokines. These events can lead to spreading of injury to adjacent segments. SCI can also lead to chronic complications, including bladder and bowel dysfunction, sexual dysfunction, neurogenic pain, and muscle spasticity. The current available treatments for SCI are limited to those that aim to ameliorate these chronic symptoms and complications (Gwak et al., 2016; Koulousakis & Kuchta, 2007). There are currently no therapies available that produce neurological improvement for SCI patients. Thus, the development of therapies seeking to restore sensory and motor function has been an active area of investigation. One approach, stem cell transplantation, aims to replace the cells and signaling factors that are lost in SCI. In the following chapter, we will discuss stem cells, with a particular emphasis on their potential role as a therapy in SCI.

Pathophysiology of SCI

The pathophysiology underlying SCI is thought to begin with an initial insult followed by a secondary injury cascade that is characterized by three overlapping phases: acute, sub-acute, and chronic phases (Table 1). The acute phase refers to the period immediately following mechanical insult that leads to compression or transection of the spinal cord. This initial event damages neurons and glial cells, disrupts membrane integrity and electrical conductance, and destroys local vasculature. These processes disturb the blood–spinal cord barrier, leading to ionic imbalance and excitotoxicity (Alizadeh, Dyck, & Karimi-Abdolrezaee, 2019). The sub-acute phase encompasses the inflammatory cascade and resultant cell death by apoptosis, ischemic necrosis, ferroptosis, and demyelination through Wallerian degeneration (Ahuja et al., 2017).

Diagnosis and Treatment of Spinal Cord Injury. https://doi.org/10.1016/B978-0-12-822498-4.00031-2

TABLE 1 Summary of events in the pathophysiology of spinal cord injury.

Stage	Key events	Consequences
Acute	Mechanical compression or transection of spinal cord	–Neuronal and glial injury –Disruption of membrane integrity –Destruction of local vasculature –Excitotoxicity
Sub-acute	Triggering of inflammatory and immune responses	–Necrosis –Apoptosis –Demyelination
Chronic	Remodeling and healing	–Glial scar –Cystic cavity

Of note, the key events and consequences can overlap between stages to some degree. However, the above framework is useful for the conceptualization of the cascade of events that follow the initial insult to the spinal cord.

The chronic phase is defined by remodeling and healing which usually produces a glial scar and cystic cavity at the lesion focus (Alizadeh et al., 2019; Pineau & Lacroix, 2007).

This influx of immune cells (such as macrophages, microglia, and neutrophils) is critical for clearing of debris and healing of the initial trauma, but they can also induce further inflammation by cytokine release and spreading of injury to adjacent segments (Kubota et al., 2012; Kumar et al., 2018). In addition to perpetuating further inflammation, immune cells also generate reactive oxygen species (ROS) that can cause oxidative damage to lipids, proteins, and DNA (Su et al., 2019). These oxidative reactions can incite further necrosis and apoptosis (Dizdaroglu et al., 2002; Hausmann, 2003). After the inflammatory process abates, a glial scar is formed from astrocytes. This glial scar serves as a physical and chemical barrier that impedes axonal regeneration and neurite growth (Ahuja, Martin, & Fehlings, 2016).

Ultimately, these processes result in the loss of three components that are critical for sub-serving sensory and motor networks of the spinal cord: neurons, myelin, and neurotrophic factors. Thus, if stem cells could be directed to differentiate into neurons, oligodendrocytes that promote myelination, or neurotrophic factor-producing cells, meaningful functional and clinical recovery may be possible.

Stem cells: A brief overview

Stem cells are characterized by their capability to undergo both differentiation and self-renewal (Tajbakhsh, Rocheteau, & Le Roux, 2009). Classification of stem cells can be based on their potential differentiation into distinct cell types. Totipotent stem cells can become any cell type in the developing embryo, as well as extra-embryonic cells like the placenta. Pluripotent stem cells have a more restricted differentiation potential and are only able to make cells of the developing embryo. In other words, pluripotent cells can become any cell in the adult body. Multi-potent cells are further restricted and are only able to mature into cell types within a particular germ layer (e.g., any cell type derived from embryonic ectoderm).

Embryonic stem cells—An overview of pre-clinical findings

During development, embryonic cells can differentiate into a multitude of different cell types that compose the different organs and organ systems of an adult animal. Thus, embryonic stem cells (ESCs) were among the first reservoirs of pluripotent stem cells to be tapped for use in SCI cell-based therapy research (Table 2).

Animal-derived ESCs

The use of rodent ESCs in animal models of SCI has produced encouraging results at the molecular and functional level. Transplanted ESCs can survive and differentiate into neurons, oligodendrocytes, and astrocytes (Lin et al., 2017; Pajer et al., 2019). Furthermore, these transplanted cells can also form new synaptic connections (Deshpande et al., 2006; Lin et al., 2017). It has been shown that introduction of rodent ESCs with biomaterial scaffolding, may improve survival of transplanted cells, greater retention of cells at the locale of injury, and facilitation of formation of new circuitry (Kourgiantaki et al., 2020; Wang et al., 2018). In addition to scaffolding, survival and maintenance of stem cells may also

TABLE 2 Summary of different stem cell types that have been investigated in pre-clinical studies or human clinical trials.

Stem Cell Type	Source	Pros	Cons
Embryonic stem cells	–Pre-implantation blastocyst	–Very broad potency	–Ethical concerns including destruction of embryo –Potential teratoma formation –Allogeneic transplantation –Potential immune reaction
Mesenchymal stem cells	–Bone Marrow –Umbilical Cord –Adipose Tissue	–Large supply of cells –Potential for autologous transplantation	–Limited potency compared to embryonic stem cells –Potential teratoma formation –Potential immune reaction
Induced pluripotent stem cells	–Adult somatic (e.g., skin or blood)	–Large supply of cells –Potential for autologous transplantation	–Requires genetic manipulation –Potential teratoma formation –Potential immune reaction

be promoted with co-transplantation with factors, such as brain-derived neurotrophic factor (BDNF) and vascular endothelial growth factor (Lu et al., 2014a; Robinson & Lu, 2017). Functionally, ESC transplanted cells have been demonstrated to improve locomotion in SCI models (Ramadan et al., 2018; Zhang et al., 2015). Lastly, there is also mounting data from SCI rodent model studies suggesting that transplanted ESCs may be able to reduce some of the long-term complications such as chronic pain and cardiovascular dysfunction (Hou et al., 2020; Jergova et al., 2016).

Human-derived ESCs

The advent of molecular protocols capable of directing human ESCs, taken from human blastocysts, to neuronal or glial fates facilitated SCI transplantation studies (Lukovic et al., 2012). Demyelination is one of the hallmarks of SCI and, thus, several investigators have pursued transplanting oligodendrocyte progenitor cells to remyelinate descending spinal cord axons. In one study, Keirstead and colleagues transplanted human ESC derived-oligodendrocyte progenitors into the spinal cord of adult rats that were either 7 days or 10 months after thoracic contusion SCI (Keirstead et al., 2005). Among rats that received the transplant 7 days after injury, the investigators observed differentiation of progenitors into mature oligodendrocytes, remyelination of axons, and improved motor functioning. Differentiation into oligodendrocytes was also seen in rats that were transplanted 10 months after injury. However, these rats failed to demonstrate signs of remyelination or locomotor improvement. These data indicate that the value of transplanting stem cells in SCI patients may depend somewhat on the time since injury. In another study, transplanted human ESCs were shown to further express neurotrophic factors such as BDNF and transforming growth factor-B2 (Zhang, Denham, & Thies, 2006). These factors are, among other things, important for axonal regeneration and neurite growth and could further contribute to the utility of human ESCs as a therapeutic agent.

ESC limitations

Taken together, there is evidence suggesting that transplanted ESCs can survive, mature, reintegrate into existing networks, and promote at least modest motor restoration in vivo. ESC studies, however, have also been accompanied by several limitations. For example, in studying ESCs, they must be collected from the inner cell mass of the blastocyst. This procedure ultimately leads to the demise of the blastocyst (Vazin & Freed, 2010) and has raised ethical concerns (Volarevic et al., 2018). Furthermore, ESC transplantation depends critically on the ability of the stem cell to differentiate specifically into a particular target cell type. When this fails to occur, one of the consequences is the generation of a teratoma, a tumor made up of somatic cells of diverse types (Nussbaum et al., 2007). The final limitation, as is the case for all forms of allogeneic transplantation, is that there always remains a definite concern for inciting an immunologic response against the transplanted cells (Swijnenburg et al., 2008).

Thus, despite the encouraging findings from ESC studies that established stem cells as a promising potential SCI therapy, ESC approaches have suffered from several drawbacks that make clinical translation difficult. For these reasons, alternative sources of stem cells have been investigated.

Toward autologous transplantation: Mesenchymal stem cells

Among these alternative sources are mesenchymal stem cells (MSC), named for their ability to mature into mesoderm derived tissues, such as bone and cartilage (Table 2). MSCs possess their own benefits and challenges distinct from ESCs. Because they can be derived from adult tissues, MSCs are not shrouded in the same ethical controversies as ESCs. MSCs, like other forms of stem cells, can be transplanted intravenously as they are attracted by inflammatory factors to the site of injury. Lastly, because transplantation can be autologous, MSC interventions would be less likely to elicit a significant immune response. With regards to drawbacks, one of the most critical is the limited potency relative to ESCs. Nevertheless, animal studies suggest that they can differentiate into cell types that have sufficient specificity to integrate into the spinal cord and induce functional gains.

Bone marrow–derived MSCs

Adult bone marrow harbors MSCs whose usual physiological role is replacing the cellular components of blood. The migratory ability of bone marrow–derived MSCs was demonstrated when murine bone marrow MSCs were injected into the lateral ventricles of neonatal mice and were found to migrate throughout different regions of the brain, such as the hippocampus, cerebellum, and brain stem (Kopen, Prockop, & Phinney, 1999). This was followed by a study in which bone marrow MSCs were retrieved from the lower extremities of rats and centrally injected into rats up to 7 days after thoracic contusion SCI (Hofstetter et al., 2002). Implanted cells differentiated toward astrocytes near the site of injury and, furthermore, gait improvements were found. Notably, more favorable effects were observed when transplantation of MSCs occurred a week after, rather than immediately after injury. Finally, in a step toward assessing the utility of human adult bone marrow MSCs, another study evaluated the effect of intravenous injection of human bone marrow MSC in SCI rat models 7 days after compression injury. The authors demonstrated with immunohistochemical analysis that the intravenously introduced bone marrow MSCs migrated to the site of injury. More specifically, the MSCs integrated within the ventrolateral white matter tracts. With respect to their role within their new home, MSCs were found to differentiate into oligodendrocytes, and increased axonal growth was observed in areas adjacent to injury. Functionally, locomotor improvement was seen at weeks 3 and 4 (Cízková et al., 2006).

Adipose tissue–derived MSCs

Adipose tissue represents another tissue source with readily available MSCs. Adipose MSCs are unique in that their effect in spinal cord recovery may be mediated by changes in vasculature. One study implanted masses of adipose MSCs from humans into a rat SCI model and found that transplanted cells released angiogenic factors that ultimately led to vascular remodeling (Oh et al., 2012). This was confirmed with another study that intravenously injected adipose MSCs from dorsal fat pads into thoracic contusion SCI model rats 8 days after injury and demonstrated angiogenesis, as well as motor recovery (Ohta et al., 2017). Another interesting feature of adipose tissue is that MSCs isolated from cryopreserved adipose tissue have been shown to exhibit similar biochemical characteristics as adipose MSCs from fresh tissue (Ohta et al., 2018). The implication here is that large stores of adipose can be collected for a tissue bank that can potentially serve as a stem cell reservoir.

Umbilical cord-derived MSCs

Lastly, MSCs derived from umbilical cord blood may also hold therapeutic potential for SCI. The utility of umbilical cell therapy for CNS injury was first introduced in the context of stroke (Chen et al., 2001) and traumatic brain injury (Lu et al., 2002). Given the promising results in these two contexts, their utility in SCI began to be investigated shortly thereafter. Umbilical MSCs have now been shown to promote improved motor function in thoracic compression and contusion SCI rat models (Saporta et al., 2003). Moreover, the specificity of the umbilical cord MSC's targeting of injured cord, if introduced intravenously, has also been well demonstrated. In the study by Saporta and colleagues, umbilical MSCs were only found in the spinal cord of SCI rats at the level of injury. The introduced cells were absent from non-injured areas of the spinal cord and, moreover, were not found in the spinal cord of non-injured rats. Importantly, similar in spirit to what has been shown for bone marrow, injection of umbilical MSCs 5 days after injury yielded superior results over injection 1 day after injury (Saporta et al., 2003). It is posited that the presence of inflammatory cytokines in the hours immediately after traumatic injury restricts the engraftment of transplanted stem cells into native tissue.

Numerous animal model and basic science studies have illustrated the potential utility of MSCs. From a bench-to-bedside translation standpoint, MSCs offer significant advantages such as mobility that allows for intravenous introduction, autologous transplantation, and relatively large available stores. Although there remains some interest in MSCs for SCI therapy, a few years after the first MSC–SCI studies were reported, advances in molecular techniques ushered in an arguably more promising source for stem cells.

Cellular reprogramming: Induced pluripotent stem cells

One of the great feats of molecular biology was the discovery of factors that could be applied to adult somatic cells and cause them to dedifferentiate (Takahashi & Yamanaka, 2006). After application of these factors (e.g., SOX2), somatic cells are transformed into pluripotent cells. These cells, termed induced-pluripotent stem cells (iPSCs), evaded two major limitations that had hindered the progress of the development of ESC therapies. First, production of induced-pluripotent stem cells does not necessitate the destruction of a blastocyst, overcoming some of the ethical concerns tied to ESC. Second, because iPSCs can be derived from the adult tissue of an SCI patient, the subsequent transplant would be autologous and would pose lower risk for an immune-mediated transplant reaction. At the outset, iPSCs looked to be a prime candidate for SCI transplant therapy (Table 2). Results from animal model studies have garnered even further advancement.

One of the first steps in attempting to design iPSC-based transplant therapies was the development of protocols that promote iPSC differentiation specifically into neurons, glia, or their precursors. Several studies have now demonstrated this capability with both murine and human iPSCs (Lu et al., 2014b; Tsuji et al., 2010). In addition to showing that neural and glial precursors could be produced from iPSC, there are mounting data that these cells can be integrated into motor networks after transplantation. In one study, murine iPSCs were transplanted into thoracic contusion SCI mice and differentiated into neurons, astrocytes, and oligodendrocytes. The transplanted cells also promoted axonal growth and remyelination, resulting in improvement of motor function (Tsuji et al., 2010). Studies of human iPSCs have likewise produced promising results. In these studies, human iPSCs derived primarily from adult fibroblasts (Lu et al., 2014b) were transformed into neurospheres or neural stem cells and transplanted into animal models of SCI. The transplanted cells were shown to survive in the recipient animal, differentiate into neurons and glia, grow elongated axons, form synapses with the host cells, produce neurotrophic factors, and engage in remyelination. In summary, human iPSCs transplanted into animal models of SCI can replace neurons, myelination, and neurotrophic factors that are lost to injury, adding to the litany of evidence that advocates for the translation of stem cell therapies to human SCI patients.

As discussed above, the use of iPSCs avoids the ethical challenges of ESCs, but iPSCs are not devoid of limitations. As is the case for ESCs, teratoma formation is also a concern in iPSCs (Gutierrez-Aranda et al., 2010). In fact, in one of the studies discussed above, by Tsuji and colleagues, the investigators categorized their iPSC-derived precursors as either safe or unsafe, prior to engraftment (Tsuji et al., 2010). In contrast to the overall positive results observed in mice that received the safe cells, teratoma formation was found in mice that received the unsafe cells. Teratoma formation would serve as a major hurdle to translating iPSCs to clinical use. Thus, alternative protocols for producing iPSC suitable for clinical use that are less likely to produce teratomas are under investigation (Deng et al., 2018). Finally, although the transplant of iPSCs can potentially be autologous rather than allogeneic, they still carry a risk for transplant reaction (Zhao et al., 2011).

Translation to the bedside

Development of a more accurate model

Since most animal SCI studies conducted to date have been limited to the setting of acute SCI, there is a paucity of evidence indicating whether stem cell transplantation can be successful in chronic SCI patients. Furthermore, most studies have utilized rodent models, where the pathophysiology and long-term functional deficits do not necessarily recapitulate what is found in humans. For example, even after severe injury, rodents are capable of some level of spontaneous recovery (Fischer & Peduzzi, 2007). These points raise the question of how well findings from such models will translate to human patients with chronic SCI and have motivated the development of animal models that more faithfully reflect the cellular and functional changes found in human patients. In one study, investigators developed a chronic SCI model with Gottingen-Minnesota minipigs (Navarro et al., 2012). Using a compression approach, investigators were able to produce stable long-term neurological deficits as well as histopathological changes like those seen in humans. This model has been recently used in a study where iPSC-derived NPCs were grafted 2.5 months after compression. Grafts were found to be capable of surviving in both autologous and syngeneic settings, and capable of differentiating into neurons several months after transplantation (Strnadel et al., 2018). Further studies like these in large animals that more accurately model human SCI will be critical for identifying the cell-based therapies that have the most potential for success in human trials.

Human studies and clinical trials

A few clinical trials examining stem cell transplantation in human SCI patients have been completed, with many others ongoing or planned (Table 3). Many of the completed trials have been early stage and were conducted with small sample sizes, and important lessons are to be gleaned. One early report described case studies on eight SCI patients that received bone marrow–derived stem cells (Geffner et al., 2008). The investigators employed multiple routes of administration: spinal cord, spinal canal, and intravenous injections. The procedure was overall safe and well tolerated. At follow-up, patients reported improved quality of life, based on the Barthel Index previously devised for use in patients in the context of stroke. In another study, Mendonca and colleagues conducted a phase I, non-randomized, uncontrolled clinical trial with 14 subjects that had complete thoracic or lumbar level SCI (Mendonça et al., 2014). The study participants received bone marrow–derived stem cell transplants and were evaluated for sensory and motor changes 6 months after the procedure.

Clinical trials were identified from https://www.clinicaltrials.gov/. Information for human clinical trials discussed in the chapter text, but not captured by our search were also included in the table if they are registered on https://www.clinicaltrials.gov/. Abbreviations: *ASIA*: American Spinal Cord Injury Association; *ISNCSCSI*: International Standards for Neurological Classification of Spinal Cord Injury; *MEP*: motor evoked potentials; *MRI*: magnetic resonance imaging; *NCT*: National Clinical Trial; *SSEP*: somatosensory evoked potentials; *UC-MSC*: umbilical cord mesenchymal stem cell.

Apart from one post-operative complication (cerebrospinal fluid leak), no patients experienced adverse events, deeming the transplantation safe. Additionally, several of the study patients demonstrated modest improvements in sensory, motor, and urologic function.

A pair of recent clinical trials made use of human central nervous system derived stem cells rather than autologous bone marrow cells. Curtis and colleagues recruited four patients with thoracic SCI for a phase 1 clinical trial of NSI-566, a neural stem cell line derived from human spinal cord (Curtis et al., 2018). The transplant procedure was well-tolerated by the study participants and, moreover, no serious adverse events were observed during the follow-up period of 18 to 27 months. Two of the four patients demonstrated motor and sensory improvements as measured by ISNCSCI scores. In one additional patient, although ISNCSCI was unchanged during follow-up, new muscle activity was detected via EMG. In another study, Levi and colleagues conducted a phase II trial of HuCNS-SC, a fetal brain-derived human CNS stem cell line, in SCI patients with cervical injury (Levi et al., 2019). The study was completed in two separate steps. First, six patients were transplanted with varying cell doses to define an optimal dose. In the second step, this derived optimal dose was applied to a treatment group of six new patients that was compared to a control group. Again, the procedure was found to be safe and feasible. Hints at motor recovery were shown in an interim analysis.

Although only a few SCI clinical trials of stem cell transplantation have been conducted, the studies carried out to date have documented safety, tolerability, and feasibility. The studies are low-powered and most did not involve a control group. Nevertheless, glimpses of motor, sensory, and urinary improvements were reported across trials that used different stem cell types for engraftment and recruited patients with varying segmental levels and time-delays since injury. These studies suggest that larger, more rigorous clinical trials with long-term follow-up are needed to determine the utility of stem cell transplantation.

The role of immunity

It is now evident that cells of the immune system become key players in the CNS in the period after SCI. Damage to the spinal cord triggers a cascade of events that recruit several immune and other intrinsic CNS cells to the site of injury. Some macrophage subtypes, for example, communicate with astrocytes to induce reactive astrogliosis (Haan et al., 2015). Macrophages that migrate to the site of injury also can produce nitric oxide that may cause damaged neurons to undergo apoptosis (Satake et al., 2000). Although the activity of immune cells is thought to limit the damage to the spinal cord, the immune response can produce unfavorable consequences and cause detrimental effects on non-damaged cells, such as nitric

TABLE 4 Areas of neuroscience in which stem cells are being investigated for therapy.

Neurological disorder	Pathophysiology	Clinical phenotype
Spinal cord injury	Mechanical, inflammatory, and ischemic insult to neurons, glia, and local vasculature	–Paraplegia, quadriplegia, paraparesis, quadriparesis –Autonomic dysfunction
Parkinson's disease	Degeneration of dopaminergic neurons in substantia nigra pars compacta	–Resting tremor –Rigidity –Bradykinesia
Huntington's disease	Loss of medium spiny neurons in the striatum	–Chorea –Loss of saccadic eye movements –Neuropsychiatric symptoms
Amyotrophic lateral sclerosis	Loss of motor neurons in the spinal cord and brain stem	–Progressive motor dysfunction

As can be appreciated from the pathophysiology column, all four disorders are characterized by loss of one or more types of cells. Stem cell therapy aims to replace or generate these lost components.

oxide induced apoptosis of healthy cells. Further, myeloperoxidase expressed by neutrophils may exacerbate injury by the generation or upregulation of hypochlorous acid, inflammatory cytokines, and apoptotic-genes (Kubota et al., 2012).

The role of the immune system has always been of interest to stem cell transplant therapeutics due to well-known issues such as allograft rejection. However, with these more contemporary observations that suggest that after SCI, there is a pro-inflammatory and pro-immune milieu that makes conditions potentially sub-optimal for stem cell growth and development, the role of immunity has become of even greater salience. The use of classic immuno-suppressive drugs, such as tacrolimus and cyclosporine, as adjuvants with stem cell transplantation have been evaluated in pre-clinical studies (Nutt et al., 2013). In select human clinical trials of stem cell transplantation, immunosuppressive regimens have also been employed (Curtis et al., 2018; Levi et al., 2019).

Applications to other areas of neuroscience

Beyond SCI, stem cells have also been explored to regenerate cells in other neurological disorders (Table 4). In the context of Parkinson's disease, which is characterized by loss of cells in the substantia nigra pars compacta, dopaminergic neurons derived from human embryonic stem cells have been transplanted into rat and mouse models of Parkinson's disease, leading to engraftment and improved motor function (Ganat et al., 2012). Clinically, there have been several reports describing outcomes for Parkinson's disease patients that underwent transplantation of stem cell-derived dopaminergic cells (Kefalopoulou et al., 2014; Schweitzer et al., 2020). These small studies have described clinical improvement in the short-term (2 years) (Schweitzer et al., 2020) and long-term (greater than a decade) (Kefalopoulou et al., 2014), but the utility of stem cells in Parkinson's disease remains uncertain without replication of these findings in controlled trials. In Huntington's disease, the underlying pathophysiology involves degeneration of GABA neurons in the basal ganglia. It has been shown in the pre-clinical setting that GABA neurons derived from ESCs can be transplanted into a mouse model of Huntington's and that transplanted cells can form dopaminergic and glutamatergic synapses, leading to motor improvement (Ma et al., 2012). In the clinical setting, however, investigations involving transplantation into human patients have had less success. Multiple studies have reported that long-term survival of grafts is limited, potentially because grafts may begin to assume a degenerative Huntington phenotype after transplant (Barker et al., 2013). Lastly, in amyotrophic lateral sclerosis (ALS), stem cells have also been used to attempt to rescue motor function or delay the widespread degeneration of motor neurons. Neural stem cells, for example, derived from human spinal cords have been used in rat models of familial ALS to delay disease progression and improve survival (Xu et al., 2006). In human patients, early-stage clinical trials involving transplantation of cells from various sources, including neural stem cells and mesenchymal stem cells, have been completed (Mazzini et al., 2015). Studies have consistently demonstrated safety and feasibility. While some transient motor improvements have been described, larger controlled trials are necessary to further assess therapeutic potential in the context of ALS.

Conclusion

The pathophysiology that underlies SCI can be curtly characterized as loss of neurons, loss of myelination, and loss of neural growth factors. Given stem cells' ability to mature into cells that can restore these lost components, they are an ideal candidate for therapy. The SCI animal model literature is rife with evidence suggesting that transplanted stem cells can survive and integrate into recipient neural networks to promote recovery. Translation of this approach to human patients represents an open frontier that should be further explored, given the encouraging results from early efforts. It is hoped that this foray yields an effective SCI therapy for patients that desperately need one.

Mini-dictionary of terms

Allogeneic: Cell, tissue, or organ that is of different genetic makeup from a particular recipient.
Angiogenesis: Generation of new blood vessels.
Apoptosis: Genetically programmed cell death.
Astrocyte: Nervous system cell responsible for maintenance of blood–brain barrier and scarring.
Autologous: Cell, tissue, or organ that is from the same recipient.
Blastocyst: Multi-cell structure that forms in the first week after fertilization.
Cytokine: Signaling molecule that allows cell to cell communication.
Excitotoxicity: Pathological overactivation of neurons.
Microglia: Cells in the nervous system that scavenge for debris.
Myelin: Sheaths that surround axons to promote action potential propagation.
Necrosis: Process of cellular death that leads to inflammation.
Neutrophil: Immune system cell responsible for defending against infection.
Neurotrophic factor: Proteins that support growth and reproduction of nervous system cells.
Oligodendrocyte: Nervous system cell responsible for generation of myelin.

Key facts for stem cells

- Stem cells can self-renew and differentiate into neurons and glia.
- Stem cell reservoirs include embryonic cells, bone marrow, adipose tissue, and umbilical cells.
- Stem cells transplanted into animal models of spinal cord injury can survive and differentiate into neurons and glia.
- Early clinical trials of stem cell transplantation have demonstrated safety and feasibility.

Key facts for spinal cord injury

- Spinal cord injury is a devastating neurological condition with limited therapeutic options.
- Spinal cord injury is characterized clinically by paraplegia, quadriplegia, paraparesis, quadriparesis, and autonomic dysfunction.
- The pathophysiology of spinal cord injury includes acute, sub-acute, and chronic stages.
- The immune system plays a critical role in the pathophysiology of spinal cord injury.

Summary points

- Transplanted ESCs can survive, mature, reintegrate into existing networks, and promote at least modest motor restoration in vivo, but there is a concern for inciting an allogeneic immunologic response against the transplanted cells.
- Despite the encouraging findings from ESC studies that established stem cells as a promising potential SCI therapy, ESC approaches have suffered from several drawbacks that make clinical translation difficult. For these reasons, alternative sources of stem cells have been investigated.
- MSCs offer significant advantages such as mobility that allows for intravenous introduction, autologous transplantation, and relatively large available stores.
- Induced-pluripotent stem cells are an attractive candidate for SCI since they do not necessitate the destruction of a blastocyst, and transplant could be autologous posing lower risk for an immune-mediated transplant reaction.
- Only a few SCI clinical trials of stem cell transplantation have been conducted, but have documented safety, tolerability, and feasibility.

- Immunomodulation can ameliorate the unfavorable consequences and cause detrimental effects on non-damaged cells after SCI, such as nitric oxide induced apoptosis of healthy cells.
- In addition to spinal cord injury, the therapeutic utility of stem cells is being explored in other neurological disorders, such as Parkinson's disease and amyotrophic lateral sclerosis.

Chapter 32

Viral vector gene therapy approaches for regeneration and repair in spinal cord injury

Simon J. O'Carroll and Connor A. Clemett

Department of Anatomy and Medical Imaging, School of Medical Sciences, Faculty of Medical and Health Sciences, University of Auckland, Auckland, New Zealand

List of abbreviations

SCI	spinal cord injury
CNS	central nervous system
AdV	adenovirus
HSV	herpes simplex virus
LV	lentivirus
AAV	adeno-associated virus
IM	intramuscular
IN	intraneural
IV	intravenous
IT	intrathecal
NGF	nerve growth factor
BDNF	brain-derived neurotrophic factor
NT	neurotrophin
BBB	blood-brain barrier
CSPG	chondroitin sulfate proteoglycan
ChABC	chondroitinase ABC
ADAMTS4	a disintegrin and metalloproteinase with thrombospondin motifs 4

Introduction

Traumatic spinal cord injury (SCI) results from a physical insult to the spinal cord. This leads to disruption of the blood supply and loss of tissue near the site of impact. Following this, there is ongoing detrimental change to the tissue, including inflammation, formation of an inhibitory scar, and inhibition of axonal regeneration and remyelination (Fig. 1). A number of approaches have been tested in pre-clinical models including increasing the intrinsic regenerative ability of neurons or removing the inhibitory molecules present after injury. Approaches include the delivery of neurotrophic factors (Keefe, Sheikh, & Smith, 2017), strategies to block inhibitory receptor signaling (Lang et al., 2015) or using enzymes to degrade inhibitory molecules (Bradbury et al., 2002). However, conventional methods of delivery of such factors have limitations, such as poor stability in vivo, poor tissue penetration, and the potential for off-target effects (Bo, Wu, Yeh, & Zhang, 2011). Viral vector gene therapy can be applied to a number of these approaches to help address these issues. This chapter describes different viral vectors that have been used to target the spinal cord, different delivery methods, and examples of how viral gene therapy has been used to effectively target therapeutic agents to the spinal cord.

Viral vector approaches

Viral vectors allow for long-term, stable, and targeted gene expression. A number of viral vectors have been trialed as a gene therapy approach to SCI repair. Each of these approaches has advantages and shortcomings (Fig. 2).

Diagnosis and Treatment of Spinal Cord Injury. https://doi.org/10.1016/B978-0-12-822498-4.00032-4

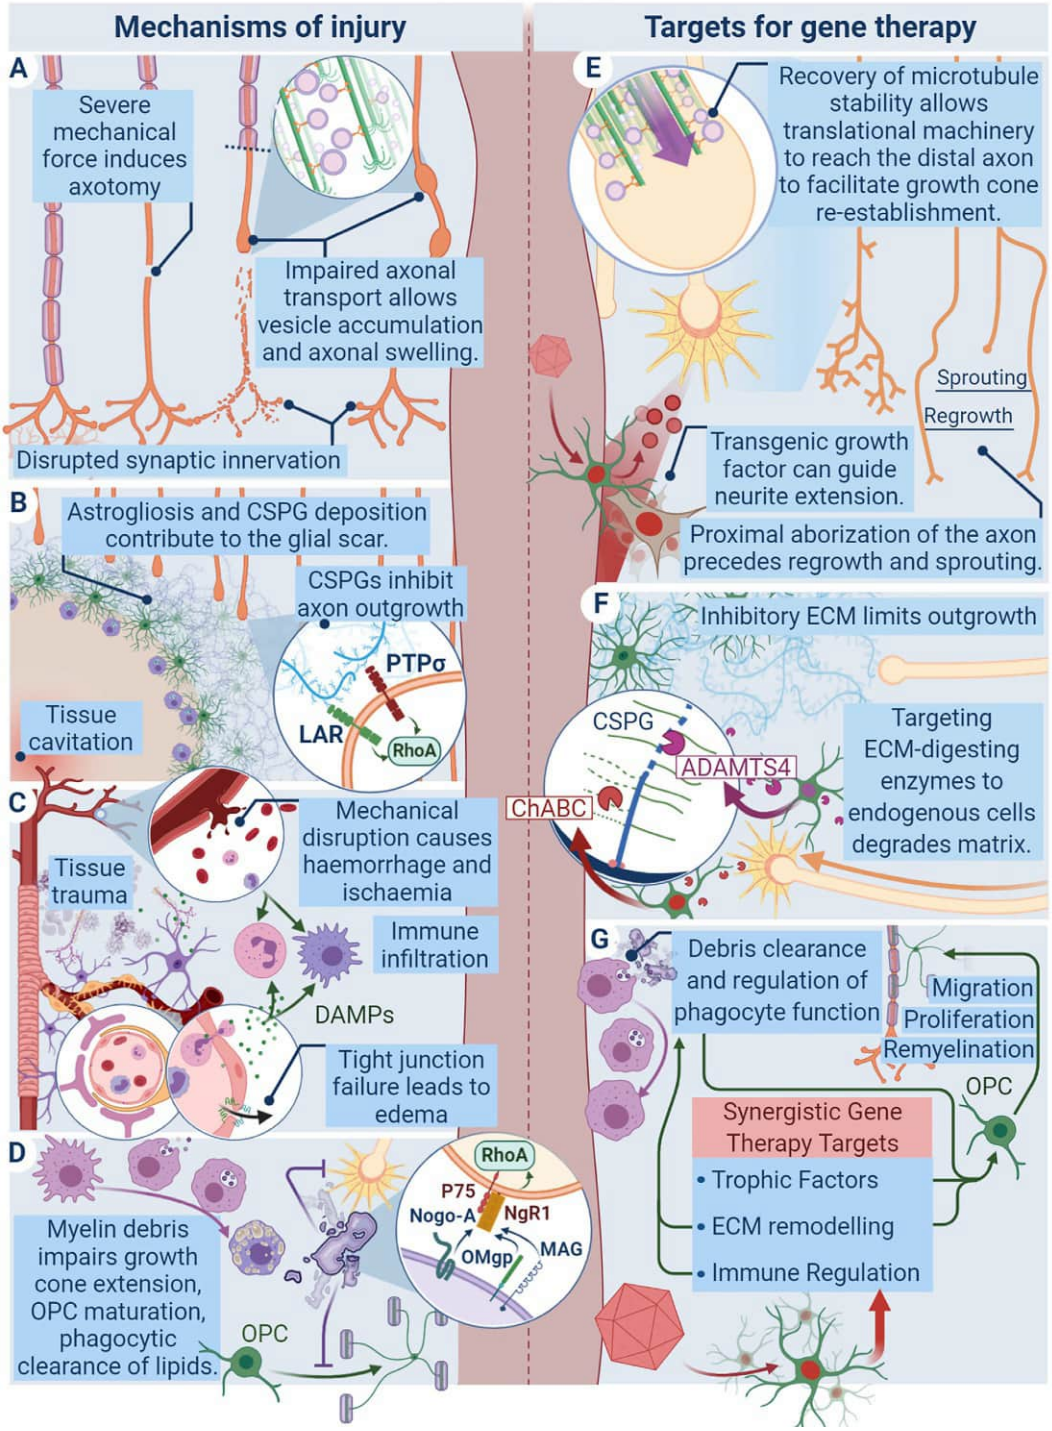

FIG. 1 Overview of traumatic spinal cord injury mechanisms and potential targets for gene-based therapies. **Mechanism**: (A) Mechanical trauma impairs axonal function leading to synaptic dysfunction. (B) ECM deposition by reactive astrocytes at the lesion border and tissue cavitation significantly impairs axonal regrowth through the injury site. (C) Vascular hemorrhage and leakage disrupts nervous tissue homeostasis whilst a large infiltrating immune cell population responds aggressively to inflammatory signals resulting from tissue trauma. (D) Myelin debris resulting from oligodendrocyte death inhibits remyelination and axon regrowth. Overwhelming of lipid metabolism within phagocytes leads to prolonged inflammatory activation. **Treatment targets**: (E) Growth cone reformation is achieved by the re-establishment of anterograde axonal transport. Neurite extension can be stimulated by the presence of transgenic growth factor cues. (F) The digestion of extracellular matrix (ECM) molecules such as chondroitin sulfate proteoglycans (CSPGs) reduces the inhibition of axonal regrowth exerted by the astroglial scar. (G) The mechanisms of many gene therapy approaches have beneficial effects upon multiple injury processes. For example, stimulation of remyelination using current treatment approaches likely results from the direct effects of transgene products upon endogenous oligodendrocyte precursors (OPCs), i.e., neurotropic factors or removal of CSPGs. However, removal of CSPGs can also regulate phagocytic phenotype and function, which in turn promotes myelin repair. Further work should take consideration the interactions of these factors and how combinational viral gene therapy could be used to optimize this beneficial synergy. *(Created with BioRender.com.)*

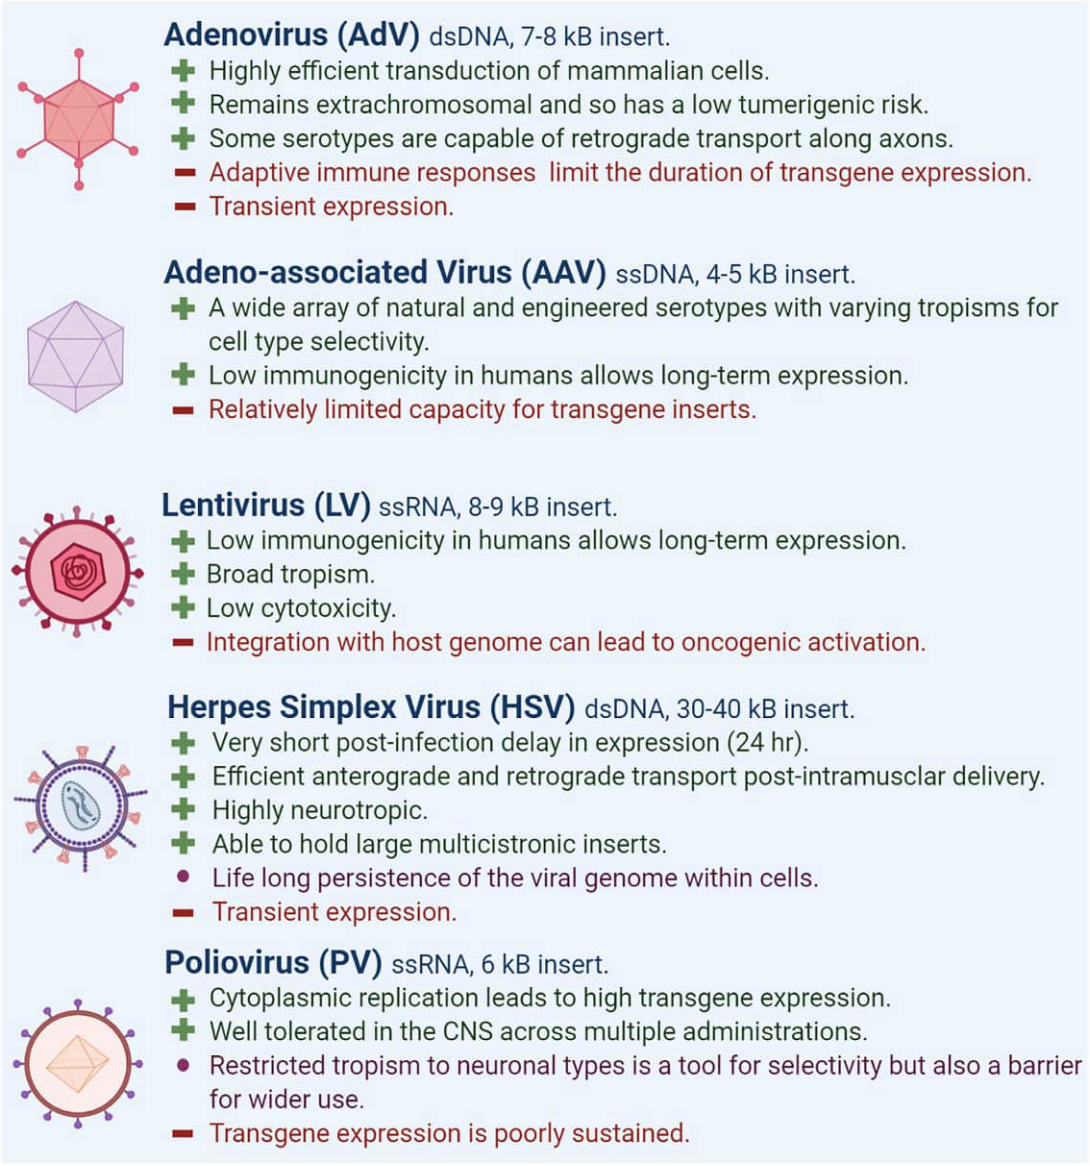

FIG. 2 Overview of viral vector systems commonly used in the treatment and study of spinal cord injury. A number of viral vectors can be used for gene delivery to the spinal cord, each of which has advantages (+) and disadvantages (−). *(Created with BioRender.com.)*

Adenovirus

Adenoviruses (AdVs) are encapsulated double-stranded DNA viruses with a 36 kb genome and therefore have the capability of holding large transgenes. They can transduce both dividing and non-dividing cells and exhibit high transduction efficiency in a wide variety of cell types. The genome remains extra chromosomal in the nucleus, thereby the transgene is not integrated into the host cell's genome, avoiding risk of tumorigenesis. However, transgene expression is only transient and expression is lost during division as the non-integrated genome is received by only one daughter cell. Also, an immune response is elicited against AdV viral antigens leading to inflammation and limiting the period of transgene expression (Byrnes, MacLaren, & Charlton, 1996).

Poliovirus

Polioviruses are small, non-enveloped RNA viruses and recombinant poliovirus replicons can be used for gene therapy (Khromykh, 2000). As infection is restricted to motor neurons in the hind brain and spinal cord these have been suggested as a potential vector for use in the spinal cord (Jackson, Cobbs, Peduzzi, Novak, & Morrow, 2001). Advantages of poliovirus include that its RNA genome is replicated in the cytoplasm, leading to very high levels of gene expression (Khromykh, 2000). Multiple inoculations of poliovirus replicons in the spinal cord has been shown to be safe, give good levels of gene expression with no functional deficits or inflammatory response. However, studies show that gene expression is not sustained (Jackson et al., 2001), although this could be of benefit if transient gene expression is required.

Herpes simplex virus

Herpes simplex virus (HSV) is an enveloped virus that contains a large (150 kb) double-stranded genome, allowing for an almost unlimited packaging capacity for transgenes. They demonstrate an exceptional capability to provide long-lived infections, with the genome being maintained extra-chromosomally in the nucleus of host cells (Glorioso & Fink, 2004). Advantages of HSV are it is neurotrophic and has a tendency to remain latent while permanently transducing target cells. The large size of the vector allows for expression of multiple genes which has been suggested as advantageous in development of effective treatments (Uchida et al., 2014). However, following transduction a number of viral proteins are expressed, leading to cytotoxicity and immune responses against targeted cells (Poulsen, Harrop, & During, 2002).

Lentivirus

Lentiviral vectors (LV) are a sub-class of retroviruses derived from human immunodeficiency viruses. Due to their ability to transduce dividing and non-dividing cells, LV vectors can transduce post-mitotic neurons, making them a powerful tool for targeting the CNS (Naldini et al., 1996) and as such have been used extensively for gene therapy targeting of the spinal cord (Uchida et al., 2014). Because LV genomes are integrated into the host genome they can provide long-term stable gene expression. While integration poses a risk of oncogenic transformation it has been suggested that this is reduced by the virus integrating into gene ends rather than promoter regions (Baum, Kustikova, Modlich, Li, & Fehse, 2006).

Adeno-associated virus

One of the most well-characterized vectors for gene therapy is derived from adeno-associated virus (AAV). Wild type AAVs are small, 4.7 kb, linear, single-stranded DNA (ssDNA) viruses in the Parvovirus family. For therapeutic use, the *rep* and *cap* genes, involved in viral replication and capsid production, respectively, are removed and replaced by an expression cassette containing therapeutic transgenes under the control of a promoter and flanked by the AAV ITRs, required for directing genome replication and packaging, forming what is termed a recombinant AAV (rAAV) (During, Young, Baer, Lawlor, & Klugmann, 2003). AAVs are considered ideal for gene therapy approaches as they are small and non-replicative, can transduce dividing and non-dividing cells, are non-pathogenic to humans and can provide long-lasting changes in gene expression. A disadvantage of AAV vectors is their small genome, impacting on the size of transgenes that can be used. A large number of clinical trials using AAV have demonstrated the relative safety of AAV gene therapy (Penaud-Budloo, François, Clément, & Ayuso, 2018).

Routes of administration

A number of different routes of administration are available for gene therapy delivery to the spinal cord (Fig. 3) and are classified as either remote or direct delivery (Hardcastle, Boulis, & Federici, 2018). Remote delivery involves non-invasive or minimally invasive routes of administration such as intramuscular (IM), intraneural (IN), intravenous (IV), and intrathecal (IT). These are dependent on the capability of specific gene therapy serotypes to travel to the spinal cord following peripheral delivery. Direct delivery involves an invasive surgical approach that directly targets a specific area of the spinal cord tissue via injection of the gene therapy and is referred to as intraparenchymal delivery.

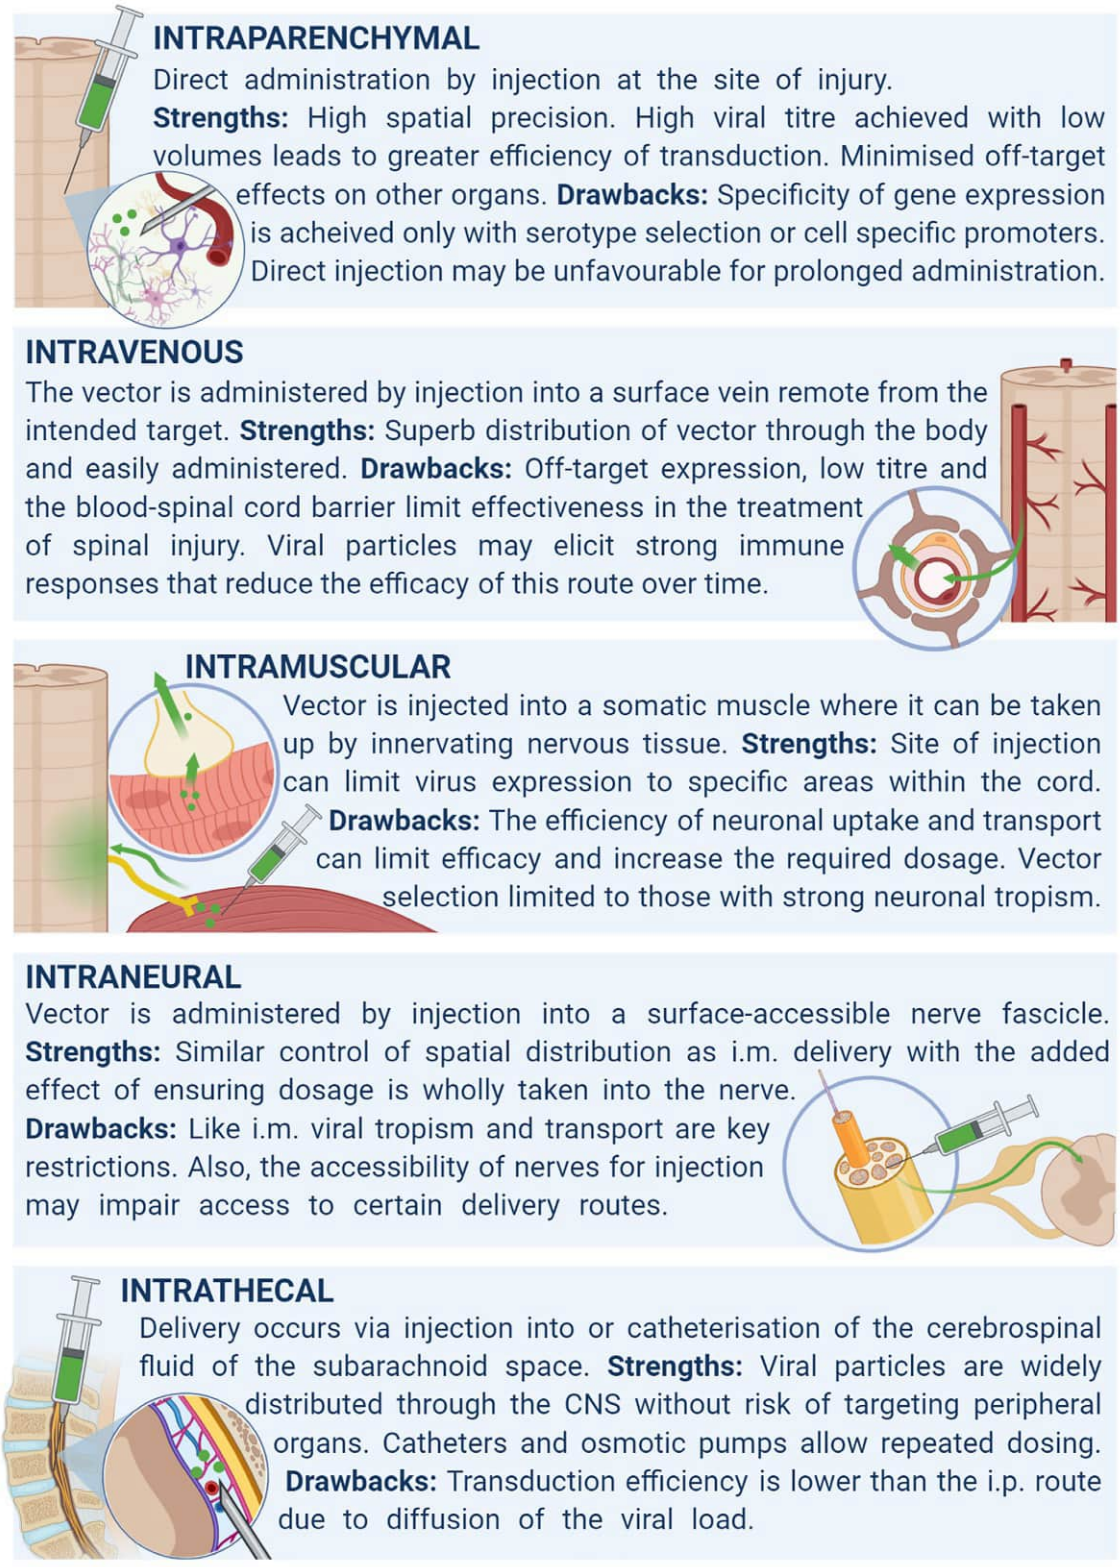

FIG. 3 Overview of common and potential gene therapy delivery routes for the treatment of spinal cord injury. Viral vectors can be delivered to spinal cord via a number of routes allowing for ease of delivery or targeted delivery depending on the desired approach. *(Created with BioRender.com.)*

Intramuscular and intraneural delivery

Retrograde transport is the transport of viral vector particles to neuronal cell bodies via axonal transport following IM or IN (e.g., sciatic nerve) injection. A number of viral gene therapies can be transported to the spinal cord from peripheral injection sites such as skin, muscle, or peripheral nerves (Franz, Weidner, & Blesch, 2012). Following injection of an HSV gene therapy into the gastrocnemius muscle of the rat, gene expression in neurons of the anterior horn spreads widely through the spinal cord and has been shown to be maintained for up to 182 days post-injection (Keir, Mitchell, Feldman, & Martin, 1995; Yamamura et al., 2000). Adenovirus has been used successfully in a number of studies to target the spinal cord via IM injection and delivery of neuroprotective compounds has been achieved (Nakajima et al., 2007; Nakajima et al., 2010). A number of AAV vector serotypes have been demonstrated to transduce neurons of the spinal cord following both IM and IN injection [reviewed in (Hardcastle et al., 2018) (Boulis et al., 2003; Towne, Schneider, Kieran, Redmond Jr., & Aebischer, 2010)]. However, retrograde transport of AAV vectors can have low efficiency. To overcome this, targeted evolution can be used to improve transport (Sun & Schaffer, 2018; Tervo et al., 2016). When Tet1, a peptide with high affinity for the tetanus toxin GT1b receptor that undergoes retrograde transport in the spinal cord, was grafted onto AAV1, enhanced axonal terminal binding and uptake was seen, with this vector showing a four-fold enhancement in retrograde transport in DRG explants (Davis et al., 2015). While IM injection is relatively easy and non-invasive, this largely restricts transduction to motor neurons or other populations in the anterior horn and so is not able to provide a more diffuse treatment. Also, the large amount of vector that would be required to transduce larger human muscles and the relatively long axons compared to rodents has been raised as challenges to this approach for vector delivery.

Intravenous delivery

A number of AAV vectors, especially AAV9 and similar serotypes have been found capable of crossing the blood-brain barrier and shown promise for delivering therapeutic agents to the whole spinal cord (Duque et al., 2009). However, systemic delivery using AAV leads to transduction of peripheral organs and there can be reduced levels of transduction due to the presence of antibodies against the virus. Questions also remain as to whether results seen in animal models will translate to humans. A vector, AAV-PHP, was found to have better transduction of the CNS after IV injection than its parent AAV9 but its ability to cross the BBB has been found to be species and even mouse strain dependent due to lack of its receptor (Ly6A) (Batista et al., 2020). No known analogue for this receptor is found in humans and such species differences may impact on the usefulness of such novel BBB-crossing AAV capsids. Also, while whole spinal cord transduction may be useful for developmental disorders, targeted transduction is likely to be of more use to treat SCI.

Intrathecal delivery

This approach allows for widespread transduction, while avoiding off-target effects (Federici et al., 2012). The vector is delivered into CSF, via the sub-arachnoid space, allowing perfusion into the spinal cord tissue. Gene therapy vectors including AAV (Zhang & Yang, 2020), adenovirus (Mannes, Caudle, O'Connell, & Iadarola, 1998), lentivirus (Thomas, Palma, & Shea, 2015), herpesvirus (Kitamura et al., 2007) and poliovirus (Jackson et al., 2001) have all been used successfully to target the injured spinal cord and delivery therapeutic agents. While intrathecal injections result in greater spatial distribution, the trade-off is a comparatively lower level of expression compared to delivery into the tissue (Mannes et al., 1998).

Intraparenchymal delivery

Intraparenchymal injection of viral vectors into the spinal cord of animal models has been widely explored and used successfully by a number of groups (Blits & Bunge, 2006). This allows for focal targeting of a vector but bio-distribution can be increased by multi-level injections to the cord. Intraparenchymal injection allows for much lower volumes of virus to be used compared to remote delivery techniques. However, a major barrier toward clinical translation is the validation of a safe surgical approach for delivery to the spinal cord in large animal models and humans. Pre-clinical studies have shown the safety of delivering AAV to the cervical spinal cord of pigs (Federici, Riley, Park, Bain, & Boulis, 2009), so this does appear to be a feasible approach.

Viral vector approaches for therapeutic delivery

Neurotrophins

Following SCI, axons fail to regenerate, at least in part due to low intrinsic regenerative capacity. This has led to a large field of study testing the use of neurotrophic factors, including nerve growth factor (NGF), brain-derived neurotrophic factor (BDNF), and the neurotrophin family (NT-3, NT-4/5), to create a growth permissive environment after an injury (Keefe et al., 2017). However, delivery of neurotrophic factors to the spinal cord has major limitations. Their short half-life and issues with crossing the BBB makes it difficult to deliver biologically relevant amounts to the spinal cord for prolonged periods of time. Also, widespread delivery of neurotrophins can lead to adverse effects (Blesch, Fischer, & Tuszynski, 2012). Viral vector delivery has been used to target neurotrophins to specific neuronal and axonal populations, either directly to the cord for expression from endogenous cells or via viral transduction of cells that are then transplanted into the cord. This has been used successfully to promote axonal regeneration and is extensively reviewed elsewhere (Blesch et al., 2012; Blits & Bunge, 2006; Bo et al., 2011; Franz et al., 2012; Uchida et al., 2014).

While axonal regrowth can be promoted by the presence of neurotrophic factors, growth beyond the spinal cord lesion site is often limited due to continual presence of growth factors and the absence of a gradient of these factors across the injury site (Franz et al., 2012). The use of gene therapy approaches has helped overcome some of these issues through allowing for spatial and temporal regulation of neurotrophin delivery. Viral gene transfer has been used successfully to establish neurotrophin gradients. Viral delivery of NT3 leads to growth of axons through a spinal cord lesion (Alto et al., 2009; Bradbury, Khemani, King, Priestley, & McMahon, 1999) and a gradient established by lentiviral BDNF delivery promoted axonal sprouting toward the highest concentration of BDNF (Bonner, Blesch, Neuhuber, & Fischer, 2010). A study by (Blesch & Tuszynski, 2007) using a tetracycline-regulatable retroviral system to control BDNF expression in transplanted fibroblasts, showed that only transient expression was required to induce axonal growth into the injury site. Viral vectors allow for the targeting of specific cell populations. Targeted evolution of AAV vectors has been successful in promoting specific cell tropism (Deverman, Ravina, Bankiewicz, Paul, & Sah, 2018). As different neurotrophins stimulate different neuronal and axonal populations, the use of engineered AAV viral vectors in conjunction with cell specific promoters would allow for specific targeting of the correct cell type and would help prevent adverse effects caused by widespread neurotrophin delivery.

CSPG

Another major hurdle preventing axon regeneration and repair after SCI is the release of growth inhibitory molecules; myelin-associated growth inhibitors, chemo-repulsive guidance molecules, and highly sulfated proteoglycans, especially chondroitin sulfate proteoglycans (CSPGs) (Bradbury & McMahon, 2006; He & Koprivica, 2004; Park, Liu, Hu, Kanter, & He, 2010). Following CNS injury, CSPGs are rapidly upregulated at the lesion site by reactive astrocytes within the glial scar (Ohtake & Li, 2015) and form a chemical barrier for axon regeneration via interaction of the sugar GAG side chains with a number of receptor proteins (reviewed in (Sharma, Selzer, & Li, 2012).

Degradation of CSPGs to overcome this inhibition is being trialed as a therapeutic intervention for SCI. Chondroitinase ABC (ChABC) is a bacterial enzyme that degrades the GAG side-chains of CSPGs. In vivo delivery of this enzyme leads to beneficial effects in a number of experimental SCI models (Bradbury & Carter, 2011) although results have been mixed, depending on the type of injury (Bartus et al., 2014). This is thought to be at least in part due to issues with enzyme stability (Bartus et al., 2014). Therefore, gene therapy approaches where cells are transduced with a ChABC viral vector have been tested as a promising tool for achieving stable delivery of the enzyme. Early attempts using gene therapy had limited success in digesting CSPGs (Cafferty, Yang, Duffy, Li, & Strittmatter, 2007; Curinga et al., 2007; Jin, Ketschek, Jiang, Smith, & Fischer, 2011). However, modification of ChABC through mutagenesis of key *N*-glycosylation sites allowed the expression and efficient secretion of active ChABC enzyme by mammalian cells (Muir et al., 2010) and a number of studies have successfully shown that lentiviral delivery of mammalianized ChABC leads to improvement in both cervical and thoracic models of SCI, reduced lesion size, improved sensorimotor function (sensory axon conduction, hindlimb function, forelimb reaching, and grasping), increased axonal conduction, and increased serotonergic and vGlut1innervation (Bartus et al., 2014; Burnside et al., 2018; Didangelos, Iberl, Vinsland, Bartus, & Bradbury, 2014; James et al., 2015; Zhao et al., 2011). While to date gene therapy approaches to deliver ChABC have not been trialed in non-rodent species, promising results in large animal models following delivery of ChABC enzyme to the injured cord have been seen. Injection of ChABC into the primate spinal cord following a C7 transection led to improved hand function (Rosenzweig et al., 2019) and a recent clinical trial using ChABC injection in canines with chronic, naturally occurring spinal cord injuries showed

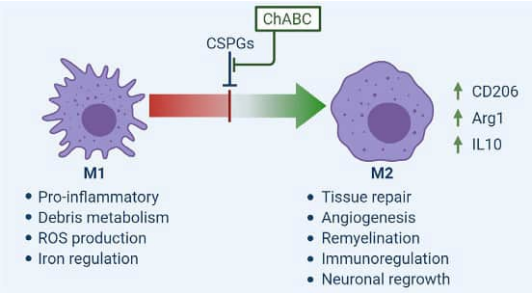

FIG. 4 CSPG digestion by ChABC causes switch to pro-regenerative inflammatory phenotype. Viral vector delivery of chondroitinase ABC modulates the inflammatory response to a pro-regenerative response, promoting tissue repair. *(Created with BioRender.com.)*

improved forelimb-hindlimb coordination (Hu, Granger, Pai, Bellamkonda, & Jeffery, 2018). This suggests that the use of gene delivery of ChABC has potential as a clinical therapy.

It is now well-understood that ECM components, including CSPGs, impact on the inflammatory response following SCI (Gaudet & Popovich, 2014). A number of studies have shown that a lentiviral approach to delivering ChABC, as well as causing extensive remodeling of the extracellular matrix and axonal regeneration, is able to modulate the post-injury immune response (Fig. 4). A study by (Didangelos et al., 2014) using lentiviral delivery of ChABC in a rat thoracic contusion model examined the expression profile of M1/M2 macrophage polarization markers. This study found that ChABC treatment had a distinct effect on the immune signature in the injured tissue, increasing expression of the pro-regenerative cytokine IL-10, with a corresponding reduction in the pro-inflammatory cytokine IL-12B. This demonstrates a distinct, ChABC-mediated anti-inflammatory response following SCI associated with large-scale removal of CSPGs. Lentiviral ChABC delivery leads to an increase in the levels of CD68 and CD206 (Bartus et al., 2014). These are markers of the M2 macrophage phenotype, which promote resolution of inflammation, enhance phagocytosis, angiogenesis, and tissue remodeling following injury (Mantovani, Sozzani, Locati, Allavena, & Sica, 2002).

While there is currently no evidence that long-term expression of ChABC using viral vectors has any detrimental effects, it is known that uncontrolled gene expression can reverse beneficial effects (Fouad, Bennett, Vavrek, & Blesch, 2013) and it has been suggested that long-term, large-scale CSPG digestion and subsequent unintended remodeling could lead to neuropathic pain (Bartus et al., 2014). Therefore, the ability to control the timing and/or duration of treatment administration afforded by the use of viral vector gene therapy would be useful in development of clinically feasible strategies. A study by (Burnside et al., 2018) used a lentivirus to deliver ChABC under the control of the tetracycline-controlled activator. This study included another development by including a glycine-alanine repeat (Hoyng et al., 2014) fused to the transactivator (GARrtTA) to avoid the immune response that can be generated against the system transactivator and which results in cytotoxic T cell-mediated removal of transgene-expressing cells (Latta-Mahieu et al., 2002). This study found short-term ChABC treatment (2.5 weeks) was sufficient to promote improvement in sensory axon conduction and ladder walking performance, however improvement in neuroplasticity of descending motor pathways required for the more complex task of forepaw reaching and grasping required 8 weeks of treatment (Burnside et al., 2018). As well as having clinical potential and allowing for the control of gene expression to avoid detrimental effects, such an approach will be useful in helping determine the most appropriate timing for an intervention, which is also crucial for clinical translation. As lentiviruses integrate into the host genome and so pose a risk of oncogenic transformation, the use of AAV vectors have been trialed for delivery of CSPG-removing enzymes. Our recent study (Griffin et al., 2020) used an AAV5 vector under the control of a GFAP promoter to deliver the human A disintegrin and metalloproteinase with thrombospondin motifs-4 (ADAMTS4) gene, which cause proteolysis of CSPG core proteins, in a rodent model of thoracic contusion SCI. This resulted in significantly decreased lesion size, increased sprouting of hindlimb corticospinal tract axons and serotonergic fiber density and improved hindlimb function when combined with hindlimb exercise rehabilitation. This study used a GFAP promoter to target expression to astrocytes is an example of how viral vector gene therapy can be used to target a specific cell types in the spinal cord to provide therapeutic effect.

Other approaches

A number of other approaches have been trialed via viral vector delivery, including modulating inhibitory receptors and signaling pathways and cell adhesion and delivery of protective molecules such as calcium sensors and anti-apoptotic proteins that have been successful in improving injury outcomes in animal models (Bo et al., 2011). Delivery of pro-

regenerative molecules such as cytokine IL-10 leads to neuronal survival and functional recovery (Zhou, Peng, Insolera, Fink, & Mata, 2009). Using lentivirus to deliver the microRNA miR-133b to the injured mouse spinal cord promotes functional recovery and down regulation of inhibitory pathways and inflammation (Theis et al., 2017). Other recent examples have targeted Hedgehog (Hh) pathway signaling via silencing of the PTC1 and PTC 2 genes (Zhang et al., 2017), apoptotic pathways via overexpression of the peroxisome proliferator activated receptor coactivator 1 alpha which leads to neuronal survival (Hu, Lang, Zhang, Ni, & Lu, 2016) and expression of the mitochondrial protein Prohibitin-1, to protect against mitochondrial dysfunction-induced damage (Li et al., 2015). Viral gene therapy has been used to deliver multiple factors. A study by Wang et al. (Wang, Lu, Chen, Shu, & Qiu, 2015), using lentivirus to deliver the pro-regenerative transcription factor KLF7 and ChABC, enhanced growth of sensory neurons to the injury site following spinal cord transection. Combinational gene therapy approaches have the potential to enhance recovery through targeting of multiple processes. For example, removal of CSPGs using ChABC improves NPC survival, oligodendrocyte differentiation, and remyelination in the presence of growth factors (Karimi-Abdolrezaee, Eftekharpour, Wang, Schut, & Fehlings, 2010; Siebert & Osterhout, 2011). ChABC also regulates macrophage phenotype (Bartus et al., 2014), which in turn promotes myelin repair (Miron & Franklin, 2014). As viral vectors have been used successfully to deliver these therapies, combinational gene therapy to optimize timing of CSPG breakdown and neurotrophic factor delivery could be used to augment the additive beneficial effects of such approaches (Fig. 1G).

In conclusion, viral gene therapy has the ability to deliver a wide-variety of treatments to the cord and with its potential to control the spatiotemporal expression of molecules, has the potential to be a powerful tool in developing effective clinical treatments for SCI.

Applications to other areas of neuroscience

This chapter provides an overview on the use of viral vectors to target gene therapies for SCI. We describe the different viral vector therapies available, methods of delivery and give an overview of how these have been used to trial potential treatments. Further, we outline how viral vector gene therapy can be used to control the spatiotemporal delivery of therapeutic agents, such as neurotrophic factors and enzymes to remove the glial scar, as a means to improve the efficacy of potential treatments. As is the case with SCI, effective delivery of treatments to the central nervous system to ensure delivery to the correct location or cell type and over the most effective timeframe has potential to improve the efficacy of treatments being developed for a number of neurotraumatic and neurodegenerative conditions. Therefore, the therapeutic potential for viral vector gene delivery is applicable to a number of other conditions including stroke (Craig & Housley, 2016), retinal disease (Campa, Gallenga, Bolletta, & Perri, 2017), Alzheimer's Disease (Sudhakar & Richardson, 2019), Parkinson's Disease (Kabra, Sharma, Kabra, & Baghel, 2018), and Huntington's disease (Estevez-Fraga, Flower, & Tabrizi, 2020).

Mini-dictionary of terms

Gene therapy: Delivery of DNA into cells to produce a therapeutic agent.

Viral vector: Tools used to deliver genetic material to cells utilizing mechanisms to efficiently transport their genomes into cells.

Remote delivery: Non-invasive or minimally invasive routes of viral vector administration.

Direct delivery: Involves an invasive surgical approach that directly targets a specific area of the spinal cord tissue via injection of the gene therapy and is referred to as intraparenchymal delivery.

Spatio-temporal delivery: An approach that allows for targeted delivery of a therapeutic agent to a specific region and for a specific period of time.

Key facts of viral vectors and spinal cord injury

- Viral vectors allow for effective delivery of a number of therapeutic agents to the spinal cord.
- Viral vectors can overcome limitations of drug delivery, such as poor stability in vivo, poor tissue penetration, and the potential for off target effects.
- A number of different viral vectors can be used to target genes to the spinal cord.
- A number of different delivery methods can be used that allow either direct or indirect delivery to spinal cord tissue.
- Viral vectors allow for spatiotemporal regulation of gene expression.

Summary points

- This chapter focuses on the use of viral vector gene therapy for delivery of therapeutic agents to treat SCI.
- A number of different viral vector gene therapies have been used to deliver therapeutic agents to the spinal cord to overcome a number of issues related to drug delivery to the spinal cord.
- Viral vectors have been used to deliver neurotrophic factors to the spinal cord and have allowed for generation of concentration gradients, which are required for growth of axons through a spinal cord lesion.
- Viral vectors have been used to deliver enzymes to breakdown the glial scar, which overcomes issues of long-term delivery and enzyme stability.
- The use of inducible systems and cell specific promoters allows for spatiotemporal control of gene delivery
- Viral vector gene therapy could be used to optimize deliver of therapeutic agents as part of a combinational approach to treatment.

List of abbreviations

AGP	α1-acid glycoprotein
AMPK	adenosine monophosphate-activated protein kinase
AQP4	aquaporin 4
BBB	Basso, Beattie, Bresnahan
ERKs	extracellular signal-regulated kinases
GFAP	glial fibrillary acidic protein
GSK-3β	glycogen synthase kinase 3 beta
HO-1	hemeoxygenase 1
ICE	interleukin 1β converting enzyme
IL	interleukin
IP	intraperitoneal
JAK-STAT	Janus kinase—signal transducer and activator of transcription
MAPK	p38 mitogen-activated protein kinase
MDA	malondialdehyde
MD-2	myeloid differentiation protein 2
NF-H	neurofilament-H
NF-κB	nuclear factor kappa B
NPC	neural progenitor cell
Nrf2/ARE	nuclear erythroid 2-related factor 2/anti-oxidant response element
NSC	neural stem cells
ROS	reactive oxygen species
SCI	spinal cord injury
SC-NPCs	spinal cord neural progenitor cell
SOD	serum superoxide dismutase
SOX-9	sex-determining region Y-box transcription factor 9
STAT	signal transducer and activator of transcriptions
TGF-β	transforming growth factor beta
TNF-α	tumor necrosis factor alpha

Introduction

Traumatic spinal cord injury (SCI) causes necrosis of the central nervous system and subsequent permanent neurological deficit. The mechanism of SCI broadly comprises two stages. First, a primary injury, attributable to the mechanical insult itself and structural damage. A secondary injury is a series of systemic and local neurochemical and physiological changes following the primary injury. The secondary injury occurs via subsequent edema, ischemia, inflammation, cytokine production, free radical damage, glial scar formation, apoptosis, and necrosis (Ormond et al., 2014). Primary injury is immediate and irreversible; in contrast, a secondary injury worsens with time and necessitates therapeutic intervention (Jo et al., 2018; Kim et al., 2014; Lee et al., 2019). The secondary injury develops within hours or days after SCI, causing neurochemical alterations that lead to neurologic functional impairments. Therapeutic modalities that promote recovery could

FIG. 1 Curcumin powder and *Curcuma longa* plant. Curcumin is a bright yellow chemical produced by the *C. longa* plants. Curcumin is the principal curcuminoid of turmeric (*C. longa*), a member of the ginger family, Zingiberaceae. It is sold as an herbal supplement, cosmetic ingredient, food-flavoring agent, and food-coloring agent.

be better understood with detailed knowledge of SCI pathophysiology (Ormond et al., 2014). Neurochemical alterations in SCI include increases in the excitatory amino acids, elevation in the calcium influx, stimulation of the calcium-dependent enzymes, generation of reactive oxygen species (ROS), and release of cytokines leading to neuroinflammation (Pouliquen, 2014). These neurochemical alterations affect the neuron and astrocyte activity, induce demyelination, modulate leukocyte infiltration, and activate macrophages (Bramlett & Dietrich, 2004; Jiang et al., 2007). In addition, secreted inflammatory cytokines and growth factors generally up-regulate the pro-survival molecules, such as nuclear factor kappa B (NF-κB) (Ghosh & Hayden, 2008). Thus, the key obstacle in the treatment and recovery process from catastrophic SCI is gliosis caused by the up-regulation of inflammation. Moreover, several studies have demonstrated the potential therapeutic role of curcumin in alleviating the second injury process.

Curcumin [1,7-bis (4-hydroxy-3-methoxyphenyl)-1,6- heptadiene-3, 5-dione] is a yellow extract obtained from *Curcuma longa* and is commonly used in India as a seasoning and food-coloring agent (Fig. 1). It is a polyphenol compound that possesses non-steroidal anti-inflammatory properties. Recent studies indicate that it may have anti-oxidant (Das & Vinayak, 2015), anti-inflammatory (Kim et al., 2014; Lee et al., 2019; Li et al., 2016), neuroprotective (Szczepanowicz et al., 2016) and anti-apoptotic effects (Liu et al., 2015) for SCI. Curcumin has emerged as a promising therapeutic drug in SCI treatment with a tendency to reduce the formation of glial scar and suppress the expression of glial fibrillary acidic protein (GFAP), thus contributing to a more favorable recovery environment (Urdzikova et al., 2016). In a recent study, curcumin inhibited the hypoxia-induced up-regulation of GFAP and neurofilament-H (NF-H) following hypoxia and down-regulated the expression of pro-inflammatory cytokines, such as tumor necrosis factor alpha (TNF-α) and interleukin 1 (IL-1) (Daverey & Agrawal, 2020).

Structure, pharmacology, and biological targets

Curcumin is a polyphenol substance that has been widely used for medicinal purposes, religious rituals, and local cuisines in the Indian subcontinent. The molecule is symmetric in structure. The keto-enol tautomer in the center, the flexible α,β-unsaturated β-diketo linker, and the terminal o-methoxyphenolic groups comprise the three main components of curcumin molecule (Fig. 2).

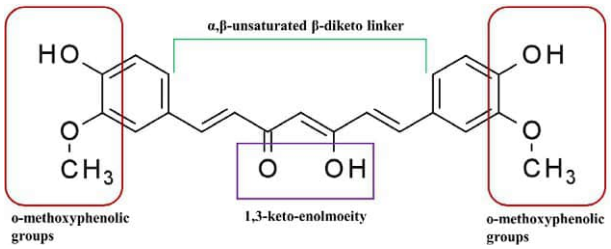

FIG. 2 Structure of curcumin. The curcumin molecule has a symmetric structure and consists of the following three main components: the keto-enol tautomer in the center; the flexible α,β-unsaturated β-diketo linker; and the terminal o-methoxyphenolic groups.

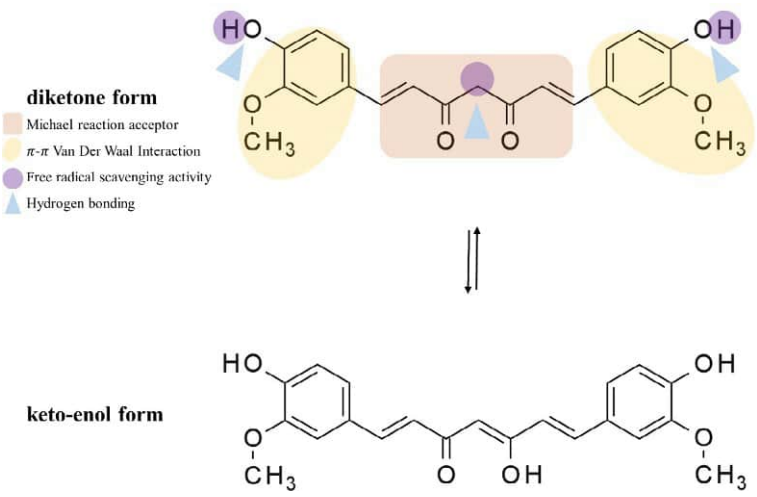

FIG. 3 The diversity of interactions that curcumin offers. Curcumin has a complex pharmacophore that serves as an anti-oxidant, can chelate metals, and can undergo Michael reaction, hydrogen bonding interactions, π-π van der Waals interactions, and free radical scavenging activity.

Curcumin has a complex pharmacophore that could act as an anti-oxidant, chelate metals, and Michael reaction (Minassi, Sánchez-Duffhues, Collado, Muñoz, & Appendino, 2013). Further, curcumin is a hydrophobic molecule comprising two ferulic acid residues linked by a methylene bridge and has high affinity for cellular membranes (Pérez-Lara, Corbalán-García, & Gómez-Fernández, 2011). Curcumin can participate in hydrogen bonding interactions with its β-diketone moiety and the substituents on the aromatic rings. The aromatic rings can also form π-π Van der Waals interactions (Gupta et al., 2011). Structure-activity relationships demonstrate that the β-diketone (keto-enol) moiety serves as a chelator for cationic metals present in the protein-binding sites and as a Michael reaction acceptor for nucleophilic groups, such as reduced selenocysteine and sulfhydryl, that form covalent bonds with curcumin (Gupta et al., 2011). The phenolic hydroxyl group is essential for the anti-oxidant action of curcumin (Priyadarsini et al., 2003; Selvam, Jachak, Thilagavathi, & Chakraborti, 2005). This group and the methylene hydrogen are crucial for free radical scavenging activity, wherein ROS and nitrogen species are subjected to electron transfer or H-atom abstraction (Priyadarsini et al., 2003). The diversity of the interactions that curcumin offers may explain its binding to multiple proteins (Fig. 3).

Molecular docking studies suggest that curcumin adopts different conformations for the maximization of these interactions, primarily via the α,β-unsaturated β-diketone moiety, and generally favors hydrophilic pockets near the cysteine residues (Ali, Haque, Saleem, & Hsieh, 2013; Gupta et al., 2011). Curcumin shares two important characteristics with the phorbol ester pharmacophore owing to the presence of the hydroxyl and carbonyl groups (Majhi, Rahman, Panchal, & Das, 2010). Removing the methylene group and carbonyl group and cutting off the pharmacophore produces a more potent molecule 1,5-bis (4-hydroxy-3-methoxiphenyl)-1,4-pentadiene-3-1 that maintains all curcumin activity (Appiah-Opong, de Esch, Commandeur, Andarini, & Vermeulen, 2008; Minassi et al., 2013).

Curcumin regulates about 100 biological targets (Das, Pany, Panchal, Majhi, & Rahman, 2011) via various mechanisms, including changing of the activity of cellular proteins via changes in the phosphorylation status (Bill et al., 2012). Generally, curcumin demonstrates its effects at concentrations above the micromolar range. This weak binding affinity has facilitated several attempts to optimize the activity of curcumin using a structural-based drug design.

Anti-inflammatory effects

After primary SCI, therapeutic strategies and outcomes depend on how we achieve reduction of inflammation and glial scar. Curcumin is a well-known anti-inflammatory molecule that evokes global inhibition of the inflammation network by suppressing transcription factors, such as NF-κB and signal transducer, as well as the activator of transcriptions (STAT) in the upstream signaling pathways of inflammatory mediators, such as prostaglandins, cytokines, and chemokines (Chandran & Goel, 2012). Curcumin may also bind directly to inflammatory mediators and enzymes in downstream inflammation pathways, such as interleukin 1β converting enzyme (ICE), TNF-α, TNF-α converting enzyme (TACE), p38 mitogen-activated protein kinase (MAPK), myeloid differentiation protein 2 (MD-2), α1-acid glycoprotein (AGP), and glycogen synthase kinase 3 beta (GSK-3β) (Elumalai, Muthaiah, & Alf, 2012; Gupta et al., 2011). Curcumin inhibited the expression of pro-inflammatory cytokines and suppressed reactive gliosis. Moreover, curcumin inhibited the generation of

transforming growth factor beta (TGF-β)1, TGF-β2, and sex-determining region Y-box transcription factor 9 (SOX-9); decreased the deposition of chondroitin sulfate proteoglycan by inhibiting the transforming growth factors and transcription factor; and improved the microenvironment that enabled nerve growth (Yuan et al., 2015). Occurring concurrently with acute inflammation and preceding fibrosis, spinal cord edema plays a crucial role in neurologic damage and patient symptoms; this is a primary reason behind the clinical usefulness of corticosteroids in SCI patients (Sanivarapu, Vallabhaneni, & Verma, 2016). An experimental rat model that was administered 40 mg/kg curcumin intraperitoneally (IP) showed reduced hemorrhage, edema, and neutrophil infiltration of the traumatic spinal cord. Curcumin also inhibited the SCI-associated aquaporin 4 (AQP4) overexpression and GFAP as well as repressed the unusual activation of the Janus kinase-signal transducer and activator of transcription (JAK-STAT) signaling pathway (Zu et al., 2014). Studies on the effect of curcumin on inflammation, fibrosis, and edema after SCI have been summarized in Table 1.

TABLE 1 Evidentiary table: anti-inflammatory properties of curcumin.

Study	Animals/ SCI	Curcumin administration	Description of study	Results
(Lee et al., 2019)	SD rats, $N = 128$ or clipping	200 mg/kg IP daily For 8 weeks	Sham ($n = 32$) SCI only ($n = 32$) SCI & Hyperglycemia ($n = 32$) SCI & Hyperglycemia & Curcumin ($n = 32$)	Curcumin regulate SOD activity increased, MDA level decreased ED-1 macrophage marker level decreased in the SCI-hyperglycemia-curcumin group Reduction in IL-6, IL-8, and TNF-a levels, the phosphorylated-ERKs Lower lesion volume, Higher spared tissue
(Ruzicka et al., 2018)	Wistar rats, $N = 131$ or balloon compression	Curcumin, 6 mg/kg; EGCG 17 mg/kg IP daily & Curcumin, 60 mg/kg; EGCG 17 mg/kg) IM weekly For 28 days	Behavioral examinations: saline ($n = 10$), curcumin ($n = 13$), EGCG ($n = 19$), curcumin + EGCG ($n = 9$) Cytokine group studies: Saline ($n = 20$), curcumin (n = 20), EGCG ($n = 20$), curcumin + EGCG ($n = 20$)	Curcumin and EGCG alone or in combination increased axonal sprouting, decreased glial scar formation, and altered the levels of macrophage inflammatory protein 1-alpha, IL-1β, IL-4, and IL-6
(Ruzicka et al., 2018)	Wistar rats, $N = 135$ or balloon compression	60 mg/kg IT weekly & 6 mg/kg IP daily For 28 days	Saline ($n = 34$), Curcumin ($n = 27$), MSC ($n = 28$), Curcumin + MSC ($n = 26$)	Curcumin + MSC facilitated axonal sprouting, and modulated expression of pro-regenerative factors and inflammatory responses
(Yuan et al., 2017)	SD rats, $N = 280$ or blunt dissection and clipping	100 mg/kg IP daily For 7 days	Sham group ($n = 70$), SCI group ($n = 70$), SCI + curcumin group ($n = 70$), SCI + DMSO group ($n = 70$)	Curcumin regulate both the NF-κb and SOX9 signaling pathways and reduce the expression of intracellular and extracellular glial scar components through dual-target regulating both inflammation and fibrosis after SCI in the rat
(Ni et al., 2015)	SD rats, $N = 48$ or clipping	100 mg/kg IP at 15 min after SCI	Sham group ($n = 16$), SCI group ($n = 16$), SCI + curcumin group ($n = 16$). $N = 16$ per group	Curcumin markedly down regulated the levels of TLR4/NF-κB inflammatory signaling pathway. Significantly ameliorated SCI induced spinal cord edema, and apoptosis
(Lin et al., 2015)	Wild-type C57BL/ 6JNarl mice, $N = 18$ or weight drop	40 mg/kg IP at 30 min after SCI	Sham control ($n = 6$), SCI ($n = 6$), SCI + curcumin ($n = 6$)	Curcumin can attenuate the down-regulation of CISD2 (CISD2 exerts anti-apoptotic and anti-inflammatory effects in neural cells) in SCI and LPS-treated astrocytes

Abbreviations: DMSO, dimethyl sulfoxide; EGCG, epigallocatechin gallate; IM, intramuscular; IP, intraperitoneal; IT, intrathecal; MDA, malondialdehyde; MSC, mesenchymal stem cells; SD, Sprague-Dawley; SOD, superoxide dismutase.

Anti-oxidant effects

Several trials have assessed the anti-oxidant properties of curcumin for SCI. There is a close association between SCI and free radical production, owing to inflammation (Hausmann, 2003). In an experimental study on the anti-oxidant effect of curcumin on SCI in rats, serum superoxide dismutase (SOD) level in the curcumin group (dose: 200 mg/kg/d orally) was higher than that in the control group and methylprednisolone group (dose: 30 mg/kg intraperitoneally). The malondialdehyde (MDA) level in the curcumin group was lower than in that the control group. Further, curcumin effectively protects the spinal cord tissues against oxidative damage (Sahin Kavaklı, Koca, & Alıcı, 2011). Curcumin acts as a free radical scavenger by donating protons to ROS and nitrogen species and quenches them via electron transfer and H-atom abstraction (Priyadarsini et al., 2003). Consequently, oxidative damage, such as lipid peroxidation is inhibited in the brain and the tissues (Priyadarsini et al., 2003; Scapagnini et al., 2011). Curcumin stimulates the intracellular anti-oxidant defense response via the indication of expression of several anti-oxidants, detoxification, and cytoprotective proteins via the unsilencing of relevant genes on the activation of the nuclear erythroid 2-related factor 2 or anti-oxidant response element (Nrf2/ARE) pathway (Scapagnini et al., 2011). Curcumin can boost the activities of anti-oxidant enzymes, such as plasma catalase, erythrocyte SOD, and plasma glutathione peroxidase (DiSilvestro, Joseph, Zhao, & Bomser, 2012). We have presented the anti-oxidant properties of curcumin as found in SCI studies in Table 2.

TABLE 2 Evidentiary table: anti-oxidant properties of curcumin.

Study	Animals or cells/SCI	Curcumin administration	Description of study	Results
(Akar et al., 2017)	Wistar rats, $N = 40$ or ischemia by clamping the aorta	100 mg/kg IP at 30 min before ischemia	Sham ($n = 10$), Ischemia-reperfusion ($n = 10$), Curcumin ($n = 10$), Solvent ($n = 10$)	Curcumin regulates MDA levels in the spinal cord decreased SOD and GPx levels increased
(Daverey & Agrawal, 2016)	HA-sp astrocytes	Cells were treated with curcumin for 24 h	H_2O_2 was used to induce oxidative stress in astrocytes 50 μM of H_2O_2 or 1 μM of curcumin or 50 μM of H_2O_2 + 1 μM of curcumin	Curcumin inhibits oxidative stress-induced cytoskeleton disarrangement, and impedes the activation of astrocytes by inhibiting up-regulation of GFAP, vimentin and Prdx6 Inhibition of oxidative stress-induced inflammation, apoptosis and mitochondria fragmentation after curcumin treatment
(Sanli et al., 2012)	Wistar rats, $N = 40$ or weight drop	300 mg/kg Single IP injection Directly after SCI	Control ($n = 8$), SCI alone ($n = 8$), Methylprednisolone sodium succinate (30 mg/kg) ($n = 8$), Curcumin + DMSO (300 mg/kg) ($n = 8$), DMSO alone (0.1 mg/kg) ($n = 8$)	Decreased lipid peroxidation and MDA levels in curcumin group
(Sahin Kavaklı et al., 2011)	Wistar rats, $N = 24$ or weight drop	200 mg/kg/d orally	SCI + no medication ($n = 8$), SCI + curcumin (200 mg/kg/d orally) ($n = 8$), SCI + methylprednisolone (30 mg/kg, IP) ($n = 8$)	SOD level in the curcumin group was higher than in the control group and methylprednisolone group MDA level in the curcumin group was lower than in the control group

Abbreviations: DMSO, dimethyl sulfoxide, HA-sp, human astrocytes cell line derived from the spinal cord; IP, intraperitoneal; Prdx6, peroxiredoxin.

Stem cell and progenitor cell proliferation

Although studies using stem cells for SCI are being actively conducted, there are still obstacles in the achievement of remarkable therapeutic results. In particular, it is essential to promote the proliferation of neural stem cells (NSC), and some studies have demonstrated the contribution of curcumin in this subject. As per a recent study, curcumin affects the proliferation of spinal cord neural progenitor cells (SC-NPCs) (Son et al., 2014). This study advocated that the anti-inflammatory effects might promote the proliferation of NPCs and showed that a lower dosage (0.1, 0.5, and 1 μM) of curcumin in the culture medium increased SC-NPC proliferation. However, a higher dosage decreased SC-NPC proliferation. They showed that SC-NPCs are more relevant to extracellular signal-regulated kinases (ERKs) and MAPK. The ERKs protein is reported to be related to cell proliferation, survival, and apoptosis (Gangwal, Bhadauriya, Damre, Dhoke, & Sangamwar, 2013), and the p38 protein played a vital role in cellular responses to external stress signals, such as anti-inflammatory reactions (Dent, 2014). Another trial on the proliferation of fetal rat NSC demonstrated the stem-cell proliferative properties of curcumin. In the cell culture (in vitro) study, curcumin increased the proliferation of fetal rat NSC at low doses (1–6 μM). Consecutive in vivo experiments, curcumin induced NPC proliferation, with the majority of subsequent differentiation into neurons/neuroblasts (Hucklenbroich et al., 2014). Ormond et al. published a study on NSC isolated from the sub-ventricular zone wherein curcumin stimulated NSC proliferation in vitro. In combination with stem-cell therapy, it induced profound recovery from severe SCI as evidenced by improved functional locomotor recovery, increased body weight, and soleus muscle mass. The findings showed that curcumin in conjunction with stem-cell therapy, synergistically improved recovery from severe SCI. Furthermore, their results indicate that the effect of curcumin extends beyond its known anti-inflammatory properties to the regulation of stem-cell proliferation (Ormond et al., 2014).

Facilitation of neurologic function recovery

In a systematic meta-analysis review, curcumin appeared to significantly improve the neurological function, as assessed using the Basso, Beattie, Bresnahan (BBB) locomotor rating scale in a random-effects model and decreased MDA using a fixed-effects model. Effect size, assessed using the BBB scale, gradually increased as the curcumin dosage was elevated (Yao et al., 2015). The meta-analysis showed that curcumin significantly improved the neurological function, as assessed using the BBB locomotor rating scale (four studies, rats $n = 132$; pooled mean difference = 3.09; 95% confidence interval, 3.40–4.45; $p = 0.04$) (Yao et al., 2015). A strength of many studies that examined the functional recovery is that a uniform scale (BBB score) was used for making inter-study comparisons, thus making extrapolations at least somewhat more reliable than those in studies using different scales (Sanivarapu et al., 2016). In an animal study involving Wistar rats, the rats were randomized into 2 groups, with 30 rats in the curcumin-treatment group and 30 in the control group. Curcumin (applied locally on the surface of the injured spinal cord immediately after an injury and then administered every day intraperitoneally) treatment improved behavioral recovery within the first week after SCI, as indicated by the improved BBB scores and plantar scores sensory performance) (Machova Urdzikova et al., 2015). This functional improvement is attributable to the anti-inflammatory effect described in the previous paragraph. In another animal study on anti-oxidative properties and function recovery, the curcumin-treatment group showed higher neuromotor scores (BBB), increased SOD, decreased MDA, and macrophage markers during seven consecutive days of intraperitoneal injections after SCI (Kim et al., 2014). One study that compared curcumin to methylprednisolone, which is often used to alleviate the secondary injury of SCI in real clinical practice, showed that curcumin was more effective than methylprednisolone after 2 weeks of the SCI, as indicated by the BBB scores. The author group concluded that curcumin has superior therapeutic potential than methylprednisolone with a prolonged treatment time in SCI (Liu et al., 2018). Thus, rat experiments and the use of BBB scores have provided considerable evidence in favor of the effectiveness of curcumin in terms of functional recover following SCI; the data have been summarized in Table 3.

Conclusion and future direction

Curcumin is a polyphenol compound that is extracted from turmeric rhizomes and is well known for its anti-oxidant and anti-inflammatory properties. These properties are helpful in the protection of neuronal tissue from secondary injury of the spinal cord, such as inflammation, cytokine production, free radical damage, and glial scar formation as well as for superior functional outcomes. Several animal experiments have shown that curcumin enhances active recovery after SCI. There are still several challenges in SCI treatment, and curcumin has several reasonable basic mechanisms as a study subject

TABLE 3 Evidentiary table: functional recovery outcomes (BBB scores) after curcumin administration.

Study	Animals/SCI	Curcumin administration	Description of study	Results
(Liu et al., 2018)	SD rats $N = 60$/weight drop	200 mg/kg IP daily For 56 days	SCI-Curcumin ($n = 27$) SCI-MP ($n = 27$) Sham group ($n = 6$)	Paralleled BBB scores between the two treatment groups (MP vs. Curcumin) on Day 56 after SCI
(Machova Urdzikova et al., 2015)	Wistar rats $N = 60$ or balloon compression	60 mg/kg Epidural locally Immediately after injury & 6 mg/kg IP daily	Curcumin treatment ($n = 30$) Controls ($n = 30$)	Curcumin treatment improved behavioral recovery within the first week following SCI (BBB scores & plantar- sensory performance scores)
(Ormond et al., 2012)	SD rats, $N = 14$ or weight drop	60 mg/kg Epidural locally Within 30 min after SCI & Weekly for 6 weeks	Curcumin treatment (n = 7), DMSO treatment ($n = 7$)	In curcumin group, improved functional scores (BBB) after 3 weeks and greater soleus weight
(Kim et al., 2014)	SD rats, $N = 36$ or clipping	200 mg/kg IP daily For 7 days	Sham ($n = 12$), SCI/vehicle ($n = 12$), SCI/curcumin ($n = 12$)	Curcumin group shows higher Neuromotor (BBB) scores 7–14 days after surgery
(Cemil et al., 2010)	Wistar rats, $N = 40$ or clipping	Curcumin: 200 mg/kg IP Immediately after injury or MP: 30 mg/kg IP Immediately after injury	Only laminectomy ($n = 8$), Laminectomy + SCI ($n = 8$), Laminectomy + SCI + MP ($n = 8$), Laminectomy + SCI + Curcumin ($n = 8$), Laminectomy + SCI + Vehicle (1 mL of rice bran oil) ($n = 8$)	Curcumin treatment improved neurologic outcome (BBB) Decreased level of tissue MDA and Increased levels of SOD, tissue structure preservation
(Lin, Lee, Chiu, & Hung, 2011)	SD rats, $N = 39$ or cord hemisection	40 mg/kg IP daily (1 day before surgery and continuing for 6 days)	Sham ($n = 5$), Vehicle (DMSO) ($n = 17$), Curcumin ($n = 17$)	The BBB scores after hemisection were improved in the curcumin group compared with the vehicle group (on 3–7 days after surgery)

Abbreviations: DMSO, dimethyl sulfoxide; IP, intraperitoneal; MP, methylprednisolone, SD, Sprague-Dawley.

compared to another experimental treatment methods such as stem-cell therapy, electrical nerve stimulation, therapeutic hypothermia that have been attempted.

Future translational research on curcumin is required to enable its clinical application. For the penetration of the blood-brain barrier, oral intake is insufficient, and there is a need to perform a study to establish an effective administration method that would allow the action of curcumin on injured neuronal tissue. Further, safety studies on high-dose

administration of curcumin are warranted. In order to improve the bioavailability of curcumin, a method, such as a megadose delivery, may be required, and dosages of previously commercialized curcumin products should be suggested. In most animal studies, continuous or intermittent curcumin administration was administered at the acute stage within 24 h of the primary injury and the chronic stage after the primary injury. Thus, we recommend future studies focus not only the dosage, but also the effective timing and duration of administration.

Applications to other areas of neuroscience

In this chapter, we have reviewed the effects of curcumin in brain ischemia and brain trauma. These two diseases are active areas in the field of neuroscience for the application of curcumin. First, in an experimental study to evaluate effect of curcumin on focal cerebral ischemic rats, a single intravenous administration of curcumin (1 and 2 mg/kg) alleviated cerebral ischemia and reperfusion injury by preventing nitric oxide-mediated blood-brain barrier disruption. Curcumin reduced the infarct volume, lowered the neurological deficit, and decreased mortality (Jiang et al., 2007). Curcumin inhibits inducible nitric oxide synthase expression and nitric oxide formation mediated by lipopolysaccharide (LPS)/TNF-α in cultured astrocytes. Based on in vitro and in vivo studies, curcumin prevents peroxynitrite-mediated blood-brain barrier damage, lowers lipid peroxidation-mediated damage, retards apoptotic cell death, and inhibits glial cell activation (Jiang et al., 2007). Curcumin potently induces the hemeoxygenase 1 (HO-1) expression and activity in rat astrocytes (Scapagnini et al., 2004). HO-1 system is well established as a defensive mechanism for neurons exposed to oxidative stress. The biochemical changes induced by curcumin treatment correlate with its ability to ameliorate changes in the locomotor activity (Wang et al., 2005). Astrocytes that are exposed to curcumin show increased expression of the phase-II detoxification enzymes, quinone reductase and glutathione S-transferase (Scapagnini et al., 2006). Thus, the inhibition of oxidative stress and neuroinflammation with curcumin improves outcomes after brain ischemia. This neuroprotective effect may be attributable to anti-apoptotic mechanisms (Zhao et al., 2010). Collectively, these studies suggest that the neuroprotective activity of curcumin in cerebral ischemia is mediated via its anti-oxidant activity (Thiyagarajan & Sharma, 2004; Zhao et al., 2010).

Studies on the effect of curcumin in traumatic brain injury indicate that this polyphenol substantially lowers oxidative damage; alters the levels of cyclic adenosine monophosphate-response element binding protein; normalizes the levels of brain-derived neurotrophic factor, and reduces the levels of adenosine monophosphate-activated protein kinase (AMPK), ubiquitous mitochondrial creatine kinase, and cytochrome C oxidase II (Sharma, Zhuang, Ying, Wu, & Gomez-Pinilla, 2009; Wu, Ying, & Gomez-Pinilla, 2006). In addition, curcumin and pyrazole curcumin derivatives suppress the increases in calcium-independent phospholipase A2 activity and decreases in the 4-hydroxynonenal levels and increase the fatty acid transport protein. Furthermore, curcumin supplementation counteracts cognitive impairments induced by traumatic brain injury and effectively restores parameters of membrane homeostasis. These results show that oxidative stress acts via the BDNF system to modulate synaptic plasticity membrane homeostasis in the injured brain and that cognition and curcumin can promote neuroprotective mechanisms (Sharma et al., 2009; Sharma, Ying, & Gomez-Pinilla, 2010; Wu et al., 2006) by facilitating endogenous up-regulation of molecules that are important for neural repair and plasticity.

Mini-dictionary of terms

Basso, Beattie, and Bresnahan scale: It is a semi-quantitative scale based on rats' locomotor response that can take on values ranging from 0 to 21. BBB scale is widely used to test behavioral consequences of SCI to the rat.

Blood-brain barrier: It is a system that has selective permeability between the blood vessels and the brain, allowing only some substances to pass through and others only through particular pathways such as transport proteins.

Curcumin: A major yellow pigment in turmeric, the ground rhizome of *C. longa*. It is a polyphenol compound that pos sesses anti-inflammatory and anti-oxidant properties and has been used for various purposes in Indian medicine for thousands of years.

Free radical scavenger: A substance that exhibits anti-oxidant effects by removing free radicals by giving hydrogen atoms to free radicals. Curcumin acts as a free radical scavenger by donating protons to ROS.

Gliosis: When the central nervous system is damaged by trauma or ischemia, it refers to the proliferation of glial cells (glia) around it occurs.

Inflammation: As one of the defense reactions of injured tissues, it refers to a complex lesion that co-occurs three things: tissue deterioration, circulatory disorders and effusion, and tissue proliferation. It is a critical process in the secondary injury of spinal cord, and curcumin has an anti-inflammatory effect.

Polyphenol: It is a substance that has more than two hydroxyls. Anti-oxidant functions are well known and are being applied to food and medical care. The catechins in green tea are typical polyphenol compounds.

Reactive oxygen species: A type of unstable molecule that contains oxygen and reacts easily with other molecules in the cell. It accumulates through the secondary injury to the spinal cord, causing DNA, RNA, and proteins damage and causing apoptosis.

Secondary injury of spinal cord: A series of systemic and local neurochemical and physiological changes (edema, ischemia, inflammation, cytokine production, free radical damage, glial scar formation, apoptosis, and necrosis) following the primary injury.

Turmeric: Ginger family perennial plant. It is about 1 m high. Several trumpet-shaped pink flowers bloom in late spring.

Key facts of curcumin

Curcumin is a neuroprotective polyphenol compound with pluripotency, oral safety, a long history of use, and reasonable cost.

Many animal experimental studies have showed that curcumin can reduce secondary damage resulting from SCI via anti-inflammatory and anti-oxidant properties as well as stem-cell mobilization.

It decreases the expression of several inflammatory and fibrotic cytokines, viable axonal fibers, GFAP, and MDA after SCI.

Further, curcumin significantly improves the neurological function, as assessed using the Basso, Beattie, and Bresnahan (BBB) locomotor rating scale in a SCI rat model.

Future translational research on curcumin is required to enable its clinical application.

Summary points

- Curcumin is a key active ingredient extracted from turmeric. Turmeric is a rhizomatous plant of the ginger family.
- Curcumin is well known for its extensive pharmacological activity, such as inflammation relief and anti-oxidant effect.
- The neuroprotective effect has been reported in several experimental studies on the animal brain and neuronal tissue.
- Curcumin is a valid and effective therapeutic agent that could alleviate the catastrophic secondary injury process of the spinal cord, namely inflammation, edema, free radical injury, fibrosis, and glial scar formation.
- This potential is supported by immune pathological results proven in several animal experiments; significantly better outcomes were produced with the evaluation using the Basso, Beattie, and Bresnahan locomotor rating scale for recovery of neurologic function.
- However, the evidence-based effectiveness of curcumin for SCI remains in the experimental stage.

Chapter 34

Use of (−)-epigallocatechin-3-gallate on spinal cord injury

Ali Reza Khalatbary
Molecular and Cell Biology Research Center, Faculty of Medicine, Mazandaran University of Medical Sciences, Sari, Iran

List of abbreviations

AGEs	advanced glycation end products
AD	Alzheimer's disease
ACR	acrylamide
AKT	protein kinase B
APP	amyloid precursor protein
AQP4	astrocyte expressing aquaporin-4
ARE	antioxidant response element
α7nAChR	alpha-7 nicotinic acetylcholine receptor
BBB	blood-brain barrier
Bax	Bcl-2-associated X protein
Bcl-2	B-cell lymphoma 2
BDNF	brain-derived neurotrophic factor
CAT	catalase
COX-2	cyclooxygenase-2
EGCG	(−)-epigallocatechin-3-gallate
eNOS	endothelial nitric oxide synthase
FASN	fatty acid synthase
FGF2	fibroblast growth factor 2
GFAP	glial fibrillary acidic protein
GDNF	glial cell line-derived neurotrophic factor
GSH-Px	glutathione peroxidase
GSK-3	glycogen synthase kinase-3
HMGB1	high-mobility group box 1 protein
IRI	ischemia-reperfusion injury
iNOS	inducible nitric oxide synthase
IL-1β	interleukin-1 beta
IL-4	interleukin-4
IL-6	interleukin-6
67LR	67 kDa laminin receptor
LPS	lipopolysaccharide
MDA	malodialdehyde
MDI	motor deficit index
MMP-9	matrix metalloproinase-9
MIP-1α	macrophage inflammatory protein 1-alpha
MPO	myeloperoxidase
NF-κB	nuclear factor Kappa B
NGF	nerve growth factor
Nrf2	nuclear erythroid 2-related factor 2
NF-L	neurofilament triplet L
NADPH-d	nicotinamide adenine dinucleotide phosphate-diaphorase
NO	nitric oxide

Diagnosis and Treatment of Spinal Cord Injury. https://doi.org/10.1016/B978-0-12-822498-4.00034-8

NOS	neuronal nitric oxide synthase
nNOS	neuronal nitric oxide synthase
NT3	neurotrophin-3
NGFR-p75	nerve growth factor receptor p75
PARP	poly(ADP-ribose) polymerase
PD	Parkinson's disease
PKC	protein kinase C
PI3K	phosphatidylinositol 3-kinase
ROS	reactive oxygen species
RhoA	ras homologue gene family member A
SCI	spinal cord injury
SOD	superoxide dismutase
TNFα	tumor necrosis factor alpha
TUNEL	terminal deoxynucleotidyl transferase dUTP nick end labeling
TLR4	Toll-like receptor 4
Trk-B	tropomyosin receptor kinase B
Trk-C	tropomyosin receptor kinase C
VEGF	vascular endothelial growth factor

Introduction

Over the past decades, a large number of polyphenolic compounds with neuroprotective effects have been described. One of the main sources of these molecules is green tea, the most widely consumed beverage next to water. The chemical composition of green tea contains a number of bioactive components, mainly including polyphenols, caffeine, and amino acids (Dulloo et al., 1999). Green tea polyphenols, generally known as catechins which make up 30% of the dry weight of green tea leaves, are the main bioactive constituents of green tea with a wide variety of beneficial health effects (Graham, 1992). The main catechins in green tea include (+)-catechin, (−)-epicatechin, (+)-gallocatechin, (−)-epigallocatechin, (+)-catechin gallate, (−)-epicatechin gallate, (+)-gallocatechin gallate, and (−)-epigallocatechin-3-gallate (EGCG) (Sutherland, Rahman, & Appleton, 2006). EGCG, chemically (2*R*,3*R*)-5,7-dihydroxy-2-(3,4,5trihydroxyphenyl) chroman-3-yl 3,4,5-trihydroxybenzoate (Fig. 1), is the most abundant composition of the tea catechins, account for 65% of the total catechin content and is thought to be responsible for the majority of biological activity of green tea extracts (Zaveri, 2006). In terms of bioavailability, EGCG is predominantly absorbed in the intestine and presented more than 77% in a free form in plasma as well as its metabolites excreted in urine after oral administration (Lee et al., 2002; Meng et al., 2002;

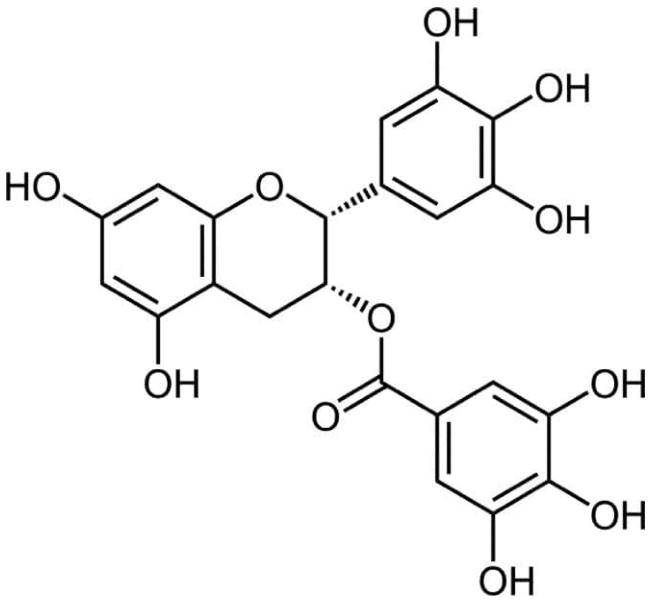

FIG. 1 Chemical structure of epigallocatechin-3-gallate. Chemical structure of epigallocatechin-3-gallate with the molar mass of 458.372 g/mol obtained from Sigma-Aldrich website. The hydroxyl groups on the B- and D-rings can bind to the free radicals and neutralized those.

Moore, Jackson, & Minihane, 2009). The half-life of EGCG in a purified form is around 3 h (Williamson, Dionisi, & Renouf, 2011). Meanwhile, it is well documented that EGCG is able to cross the blood-brain barrier (BBB) and can reach to nervous tissue even at a very low concentration, the first requirement of a dietary compound to apply neuroprotective effects (Lin, Wang, Tseng, Sung, & Tsai, 2007; Pervin et al., 2017). Several experimental studies have shown that EGCG can afford neuroprotection against brain (Itoh et al., 2011) and spinal cord (Urdzikova et al., 2017) injuries, neurodegenerative diseases (Xu, Langley, Kanthasamy, & Reddy, 2017), and peripheral nerve injuries (Renno, Benov, & Khan, 2017). These beneficial effects have been mainly attributed to free radical scavenging or anti-oxidant, anti-inflammatory, and anti-apoptotic properties of EGCG (Ohishi, Goto, Monira, Isemura, & Nakamura, 2016; Oliveira, Nabavi, Daglia, Rastrelli, & Nabavi, 2016; Weinreb, Amit, Mandel, & Youdim, 2009). In this regard, it is well known that green tea catechins due to the hydroxyl groups on the B- and D-rings of the galloylated catechins can bind to the free radicals and neutralized those (Salah et al., 1995). On the other hand, scavenging effects of EGCG lead to attenuation of nuclear factor kappa B (NF-κB) activity (Ohishi et al., 2016), which regulates genes involved in inflammatory processes such as tumor necrosis factor alpha (TNFα), cyclooxygenase-2 (COX-2), and interleukin-1 beta (IL-1β), beside modulation of nitric oxide synthase isoforms (Lawrence & Fong, 2010). Also, catechins have proven to modulate apoptosis at various points in the sequence and messengers, and so regulate the mitochondrial membrane permeabilization (Kalfon, Youdim, & Mandel, 2007; Mandel, Maor, & Youdim, 2004).

In this chapter, we have reviewed the neuroprotective effects of EGCG and its molecular mechanisms responsible for the neuroprotection following spinal cord injury (SCI). Meanwhile, we also compared the neuroprotective effects of EGCG in SCI to other neurological disorders.

In vivo studies

SCI is a complex multifactorial process caused first by ischemia or mechanical trauma and then by various mechanisms of secondary injury (Amar & Levy, 1999). The neurological outcome of SCI depends on the extent of secondary cellular, molecular, and biochemical cascades such as oxygen free radical-induced lipid peroxidation, inflammatory reaction, and apoptosis (Hall, 1993; Liu et al., 1997; Popovich, Wei, & Stokes, 1997). In recent years, much attention has been paid to secondary injuries, as they appear to be prone to therapeutic interventions that may include the use of natural antioxidants, anti-inflammatory, and anti-apoptotic agents (Khalatbary, 2014) such as EGCG (Table 1). In this regard, our previous studies have shown that intraperitoneal injection of EGCG (50 mg/kg, i.p., immediately and 1 h after SCI)

TABLE 1 Neuroprotective effects of epigallocatechin-3-gallate on spinal cord injury.

Model of injury	Treatment schedule	Finding	Possible mechanism	Author	Year
Weight-drop method	50 mg/kg, intraperitoneal, immediately and 1 h after spinal cord injury	Decreased bcl-2-associated X protein and increased b-cell lymphoma 2 expression	Anti-apoptotic activity	Khalatbary et al.	2010
Weight-drop method	50 mg/kg, intraperitoneal, immediately and 1 h after spinal cord injury	Decreased tissue lipid peroxide level	Anti-oxidant activity	Khalatbary and Ahmadvand	2010
Weight-drop method	50 mg/kg, intraperitoneal, immediately and 1 h after spinal cord injury	Attenuated tumor necrosis factor alpha, interleukin-1 beta, Nitrotyrosine, inducible nitric oxide synthase, cyclooxygenase-2 and poly (ADP-ribose) polymerase expression, and decreased myeloperoxidase activity	Anti-inflammatory activity	Khalatbary and Ahmadvand	2011
Vascular clip method	100 mg/kg, between 24 and 72 h after spinal cord injury	Down-regulated astrocyte expressing aquaporin-4 and glial fibrillary acidic protein	Anti-edema effect	Ge et al.	2013

Continued

TABLE 1 Neuroprotective effects of epigallocatechin-3-gallate on spinal cord injury—cont'd

Model of injury	Treatment schedule	Finding	Possible mechanism	Author	Year
Vascular clip method	100 mg/kg, intraperitoneal, immediately after spinal cord injury	Reduced the releasing of tumor necrosis factor alpha and interleukin-1 beta, decreased the water content	Regulating p38MAPK\NF -κB \AQP4 signaling pathway	Tao and Zhu	2013
Weight-drop method	Intrathecal administration of 10 or 20 mg/kg, immediately after spinal cord injury	Improved locomotor function	Up-regulation of brain-derived neurotrophic factor and glial cell line-derived neurotrophic factor	Tian et al.	2013
Weight-drop method	20 mg/kg/hour for continuous 36 h, intravenous, in acutely (initiated within 4 h post-trauma 0 time) and chronically (initiated after 12 months of spinal cord injury onset	Improved motor and sensory functions	Reduced lesion size area	Renno et al.	2014
Weight-drop method	30 mg/kg, intraperitoneal, 30 min after and daily during the first week post-spinal cord injury	Reduced thermal hyperalgesia and gliosis	Via RhoA and FASN pathway	Álvarez-Pérez et al.	2016
Balloon compression method	Intra-spinal injection of 50 mg/kg, immediately and then weekly for up to 28 days	Attenuated nuclear Factor Kappa B pathway and increased gene expression of fibroblast growth factor 2 and vascular endothelial growth factor	Enhanced neuroregeneration	Urdzikova et al.	2017
Weight-drop method	50-mg/kg, intraperitoneal, before and after ischemia-reperfusion injury	Decreased malodialdehyde, attenuated caspase-3, tumor necrosis factor alpha, and inducible nitric oxide synthase, reduction of motor deficit index	Anti-inflammatory and anti-apoptotic activity	Ahadi et al.	2019

A summary of in vivo studies on the neuroprotective effects of epigallocatechin-3-gallate against spinal cord injury, along with treatment schedules, findings, and related molecular mechanisms, is presented in this table.

can protect spinal cord tissue and improve behavioral function after traumatic and ischemia-reperfusion injury (IRI) in rats (Ahadi, Zargari, & Khalatbary, 2019; Khalatbary & Ahmadvand, 2010; Khalatbary et al., 2010). In regard to mechanisms of neuroprotective effects of EGCG, our results revealed that malodialdehyde (MDA) levels as an index of tissue lipid peroxidation, an important pathologic event in post-traumatic neuronal degeneration, were significantly decreased in traumatized spinal cord tissue after EGCG treatment (Khalatbary & Ahmadvand, 2010). It is well documented that EGCG due to hydroxyl groups can bind to the free radicals and neutralize those, while can indirectly increase the body's endogenous antioxidants (Salah et al., 1995). We detected immunohistochemically anti-apoptotic properties of EGCG with decreasing pro-apoptotic protein Bax and increasing anti-apoptotic protein Bcl-2 staining in EGCG-treated rats, which was correlated with terminal deoxynucleotidyl transferase dUTP nick end labeling (TUNEL) staining method (Khalatbary et al., 2010). Also, our other study showed that EGCG treatment (50 mg/kg, i.p., immediately and 1 h after SCI) attenuated pro-inflammatory cytokines such as TNFα and IL-1β in traumatized spinal cord tissue (Khalatbary & Ahmadvand, 2011). In line with the anti-inflammatory properties of EGCG, Ge et al., 2013 documented that EGCG treatment (100 mg/kg, between 24 and 72 h after SCI) decreased spinal tissue edema through down-regulation of astrocyte expressing

aquaporin-4 (AQP4), which plays a critical role in the transport of water from blood/CSF to spinal cord parenchyma, and through down-regulation of glial fibrillary acidic protein (GFAP) as a specific marker of astrocytes. Also, another study found that attenuated NF-κB pathway is a pivotal anti-inflammatory affect of EGCG (intra-spinal injection of 50 mg/kg EGCG immediately and then weekly for up to 28 days) after SCI (Urdzikova et al., 2017). Meanwhile, this study showed a significant increase in the gene expression of fibroblast growth factor 2 (FGF2) and vascular endothelial growth factor (VEGF) after SCI. Tao and Zhu (2013) documented that EGCG (100 mg/kg, i.p., immediately after SCI) can protect secondary SCI by potential mechanism of regulating p38MAPK\NF -κB\AQP4 signaling pathway and thus reduce edema after SCI in rats. Also, another study documented that intrathecal administration of EGCG (10 or 20 mg/kg immediately after SCI) can significantly improve locomotors recovery, which may be related to the inhibition of Bcl-2-associated X protein (Bax) and to the up-regulation of brain-derived neurotrophic factor (BDNF) and glial cell line-derived neurotrophic factor (GDNF) (Tian et al., 2013). Studies have shown that EGCG has beneficial effects not only on the tissue destruction but also on behavioral and functional outcome, so that intravenous infusion of EGCG (20 mg/kg/hour for continuous 36 h) in acutely (initiated within 4 h post-trauma 0 time) and chronically (initiated after 12 months of SCI onset) spinal cord injured rats improved significantly motor and sensory functions measured using Basso-Beattie-Bresnehan behavioral score test, Louisville forced swim test, and pain behavior assessment tests (Renno et al., 2014). One of the common complications of SCI is neuropathic pain. About the effect of EGCG on neuropathic pain, Álvarez-Pérez et al. (2016) documented that short time EGCG treatment (30 mg/kg i.p., 30 min after and daily during the first week post-SCI) reduced thermal hyperalgesia and gliosis via ras homologue gene family member A (RhoA) and fatty acid synthase (FASN) pathway. In this regard, it is mentioned that some biological properties of EGCG are attributed to its inhibitory action on FASN (Singh, Shankar, & Srivastava, 2011). In another study, the synergistic effects of curcumin and EGCG in an animal model of acute SCI were investigated (Ruzicka et al., 2018). Results of this study revealed that combination of curcumin and EGCG reduced glial scar formation, increased axonal sprouting, and changed the amount of macrophage inflammatory protein 1-alpha (MIP-1α), IL-1β, interleukin-4 (IL-4), and interleukin-6 (IL-6). Recently, our laboratory assessed the neuroprotective effects of EGCG on spinal cord IRI in rats (Ahadi et al., 2019). The level of MDA was significantly reduced in EGCG-treated rats. Attenuated caspase-3 (Fig. 2), TNFα (Fig. 3), and inducible nitric oxide synthase (iNOS) expression could be significantly detected in the EGCG-treated rats. Also, EGCG reduced the extent of degeneration of the spinal cord neurons, in addition to a significant reduction of motor deficit index (MDI). Overall, the behavioral, biochemical, and histopathological evidences demonstrated that pre- (50 mg/kg, i.p., before IRI) and post-ischemic (50 mg/kg, i.p., after IRI) treatment with EGCG had protective effects against spinal cord IRI in rats.

In vitro studies

A number of in vitro studies regarding EGCG's neuroprotection and its underlying molecular mechanisms in neural cells are starting to accumulate which summarized in Table 2.

In regard to anti-apoptotic effects of EGCG, some studies indicated that EGCG led to significant inhibition of apoptosis in PC12 cells by scavenging reactive oxygen species (ROS), modulating cytochrome *c* and caspases, activation of phosphoinositide 3-kinase (PI3K), activation of survival-promoting pathways, and inhibition of glycogen synthase kinase-3 (GSK-3) (Hou et al., 2008; Jung, Han, et al., 2007; Jung, Mo, et al., 2007; Koh et al., 2003; Mandel, Reznichenko, Amit, & Youdim, 2003; Nie, Cao, & Zhao, 2002; Nie, Jin, Cao, Shen, & Zhao, 2002; Srividhya & Kalaiselvi, 2013). Also, studies showed that EGCG has a protective effect on cell death in SH-SY5Y (or SHSY-5Y) cell line through inhibiting ROS production and caspase activity along with activation of protein kinase C (PKC) (Avramovich-Tirosh et al., 2007; Jeong et al., 2004; Levites, Amit, Youdim, & Mandel, 2002; Tai & Truong, 2010). EGCG protects N18D3 neural cells from quinolinic acid-induced apoptosis by regulation of phosphatidyl inositol 3-kinase (PI3K) and modulation of pro- and anti-apoptotic genes due to decreased intra-cellular calcium levels and nitric oxide (NO) production (Zhang et al., 2014). Results of a study showed that EGCG protects the neuronal cells against human prion protein-induced damage through inhibiting Bax and cytochrome *c* translocation and autophagic pathways in primary neuron cells (Lee et al., 2015). Recently, it was documented that EGCG reduced amyloid beta-induced neurotoxicity via inhibiting endoplasmic reticulum stress-mediated apoptosis in SH-SY5Y cells in a dose-dependent manner which is contributed to the down-regulation of cleaved-caspase-3 and -12 (Du et al., 2018).

In regard to microglial activation, a study indicated that EGCG exerts significant protection against microglial activation-induced neuronal injury through the down-regulation of iNOS and TNFα expression (Li, Huang, Fang, & Le, 2004).

In regard to antioxidant properties of EGCG, in vitro study revealed that EGCG treatment decreased MDA level, up-regulated superoxide dismutase (SOD) and catalase (CAT) levels against advanced glycation end products (AGEs)-induced

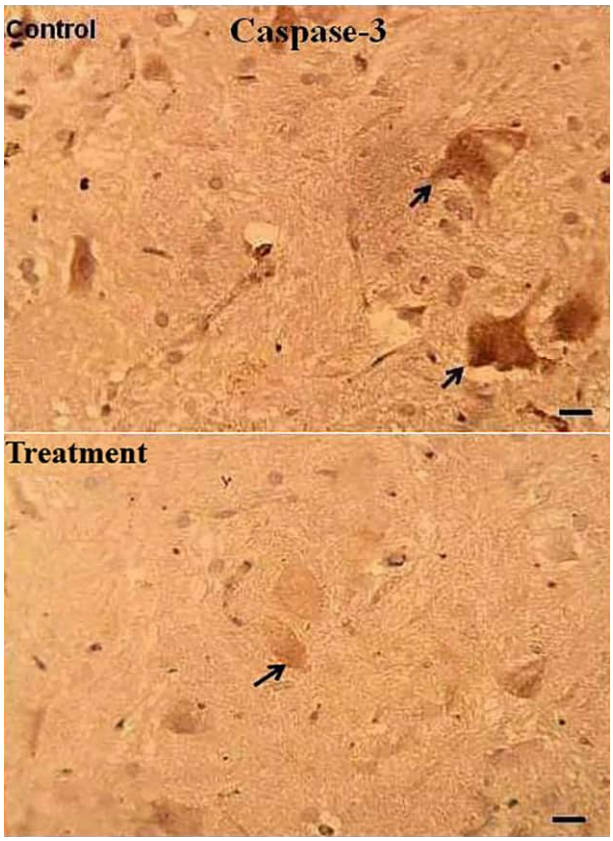

FIG. 2 Immunohistochemical staining of casepase-3. Light photomicrographs show immunohistochemical expression of caspase-3 as an index of apoptosis in control and epigallocatechin-3-gallate treatment groups after spinal cord injury (magnification, ×200). The positive staining of caspase-3 is presented by a brown color of cytoplasm (arrows). This figure prepared in our laboratory.

injury in neuronal cell culture (Lee & Lee, 2007). Also, it was documented that EGCG decreased markedly ROS production via the SIRT1/PGC-1α signaling pathway in 1methyl4-phenyl-pyridine (MMP+)-induced PC12 cells damage (Ye et al., 2012). Evaluation of EGCG's effects on acrylamide-induced cytotoxicity in PC12 cells showed that EGCG inhibited the cytotoxicity of acrylamide and increased the cell viability (Esmaeelpanah, Razavi, Vahdati Hasani, & Hosseinzadeh, 2018).

In regard to anti-inflammatory properties of EGCG, in vitro studies also revealed that EGCG treatment potently inhibited lipopolysaccharide (LPS)-activated microglial secretion of TNFα and significantly exerted anti-inflammatory effects partly as a suppressor of TNFα signaling via the NF-κB pathway in SH-SY5Y (Li et al., 2004) and RPE cells (Fu & Koo, 2006).

It is well known that anti-oxidants can also affect the stem cells differentiation and potency. In this regard, using the PC12 cell model showed for the first time that low concentration of EGCG and unfractionated green tea polyphenols potentiate nerve growth factor (NGF)-induced and BDNF-induced neuritogenesis likely through induction sub-lethal levels of ROS or dependent on 67 kDa laminin receptor (67LR) and H_2O_2 (Gundimeda et al., 2014; Gundimeda, McNeill, Schiffman, Hinton, & Gopalakrishna, 2010).

Applications to other areas of neuroscience

It is well known that EGCG has neuroprotective effects in another neurological disorder such as brain injury, nerve injury, and neurodegenerative diseases (Table 3).

In regard to brain ischemia, it was documented that EGCG through deoxidizing peroxynitrate/peroxynitrite attenuates NO-3/NO-2 concentration without affecting blood flow (Nagai et al., 2002). Another study demonstrated that EGCG due to attenuation of the malondialdehyde level and oxidized/total glutathione ratio protects brain tissue against transient middle cerebral artery occlusion (Choi, Kim, Lee, Kim, & Kim, 2004). A possible mechanism involved in the neuroprotective

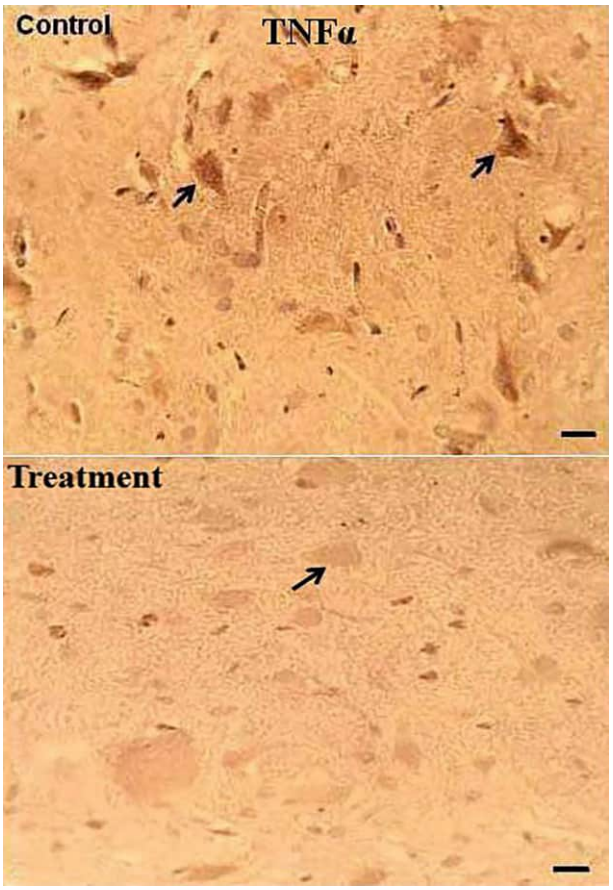

FIG. 3 Immunohistochemical staining of tumor necrosis factor alpha. Light photomicrographs show immunohistochemical expression of tumor necrosis factor alpha (TNFα) as an index of inflammation in control and epigallocatechin-3-gallate treatment groups after spinal cord injury (magnification, ×200). The positive staining of TNFα is presented by a brown color of cytoplasm (arrows). This figure prepared in our laboratory.

effect of EGCG is inhibition of matrix metalloproinase-9 (MMP-9) activity which plays an important role in the pathophysiology of brain ischemia (Park et al., 2010). Also, EGCG exerts protective effect via the activation of the nuclear erythroid 2-related factor 2 (Nrf2) against cerebral ischemia (Han et al., 2014). A further study showed that EGCG promotes angiogenesis via up-regulation of the Nrf2 signaling pathway in the early stage of ischemic stroke (Bai et al., 2017). Modulation of the inflammation-related molecules such as TNFα, IL-1β, IL-6, NF-κB /p65, COX-2, and iNOS is another possible mechanism of action of EGCG following focal cerebral ischemia/reperfusion injury (Zhang, Li, Jiang, Chen, & Huang, 2015). It was found that EGCG also preserves mitochondrial energetics (complex I—V) and citrate synthase activity after brain ischemia (Sutherland et al., 2005). While, it was documented that EGCG through eliminating free radical generation, inhibiting apoptosis, and increasing neural stem cells protects brain against traumatic injury in rats (Itoh et al., 2011, 2012, 2013).

In regard to nerve injury, results of a study showed significantly higher neurofilament triplet L (NF-L) protein expression in EGCG-treated rats compared to non-treated rats following optic nerve crush injury (Xie et al., 2010). Also, EGCG through attenuation of nicotinamide adenine dinucleotide phosphate-diaphorase (NADPH-d)/neuronal nitric oxide synthase (nNOS) increased motor neuron survival time following peripheral nerve crush injury in rats (Wei et al., 2011). Intrathecal injection of EGCG improved pain-like behaviors through decreasing NF-κB, Toll-like receptor 4 (TLR4), TNFα, high-mobility group box 1 protein (HMGB1), and IL-1β following chronic constriction injury (Kuang et al., 2012). EGCG due to the down-regulation of apoptosis related genes, up-regulation of glutathione reductase, and up-regulation of survivin gene accelerates nerve regeneration and improves functional recovery following rat sciatic nerve crush injury (Renno et al., 2017; Renno, Al-Maghrebi, Rao, & Khraishah, 2015). Also, Renno et al. documented that the EGCG neuroprotective effects are mediated through the modulation of BDNF, GDNF and neurotrophin-3 (NT3) neurotrophic factor and their receptors tropomyosin receptor kinase B (Trk-B), tropomyosin receptor kinase C (Trk-C), and nerve growth factor receptor p75 (NGFR-p75) following sciatic nerve crush injury (Renno, Khan, & Benov, 2016).

TABLE 2 In vitro neuroprotective effects of epigallocatechin-3-gallate.

Model of induction	Cell type	Finding	Possible mechanism	Author	Year
Apoptosis	PC12	Inhibited apoptosis	Modulation of cytochrome *c* and caspases, activation of phosphatidylinositol 3-kinase and survival-promoting pathways, inhibition of glycogen synthase kinase-3	Nie et al., Koh et al., Mandel et al., Jung et al., Hou et al., Strividhya and Kalaisali	2002a, 2002b, 2003, 2003, 2007a, 2007b, 2008, 2013
Apoptosis	SH-SY5Y	Inhibited apoptosis	Inhibition of reactive oxygen species production and caspase activity, activation of protein kinase C	Levites et al., Jeong et al., Avramovich-Tirosh et al., Tia and Truong	2002, 2004, 2007, 2010
Apoptosis	N18D3	Attenuated apoptosis	Regulation of phosphatidylinositol 3-kinase and modulation of pro- and anti-apoptotic genes	Zhang et al.	2014
Apoptosis	Primary neuron cells	Attenuated apoptosis	Inhibition of Bcl-2-associated X protein and cytochrome *c* translocation and autophagic pathways	Lee et al.	2015
Apoptosis	SH-SY5Y	Reduced apoptosis	Inhibiting endoplasmic reticulum stress-mediated apoptosis	Du et al.	2018
Microglial activation	SH-SY5Y	Inhibited LPS-activated microglial secretion of nitric oxide and tumor necrosis factor alpha	Down-regulation of inducible nitric oxide synthase and tumor necrosis factor alpha expression	Lee et al.	2004
Oxidative stress	Neuronal cells culture	Up-regulated superoxide dismutase and catalase levels, decreased malodialdehyde and carbonyl levels, and advanced glycation end products formation	Antioxidative properties and interfering with AGEs-RAGE interaction mediated pathways	Lee and Lee	2007
Oxidative stress	PC12	Decreased reactive oxygen species production	via the SIRT1/PGC-1α signaling pathway	Ye et al.	2012
Oxidative stress	PC12	Inhibited the cytotoxicity of acrylamide and increased the cell viability	Without providing possible mechanisms	Esmaeelpanah et al.	2018
Inflammation	SH-SY5Y and ARPE-19	Anti-inflammatory effects	Suppression of tumor necrosis factor alpha signaling via the nuclear Factor Kappa B pathway	Li et al., Fu and Koo	2004, 2006
Neurogenesis	PC12	Potentiated nerve growth factor- and brain derived neurotrophic factor-induced neuritogenesis	Involvement of sub-lethal levels of reactive oxygen species or dependent on 67 LR and H2O2	Gundimeda et al.	2010, 2014

A summary of in vitro studies on the neuroprotective effects of epigallocatechin-3-gallate with related molecular mechanisms is presented in this table.

TABLE 3 Neuroprotective effects of epigallocatechin-3-gallate against other neurological disorders.

Model of injury	Treatment schedule	Finding	Possible mechanism	Author	Year
Brain injury	50 mg/kg, intraperitoneal, immediately after ischemia	Deoxidizing peroxynitrate/ peroxynitrite without affecting blood flow	Attenuation of NO_3^-/ NO_2^-	Nagai et al.	2002
Brain injury	25 mg and 50 mg/kg, intraperitoneal, immediately after ischemia	Attenuated malodialdehyde level and oxidized/total glutathione ratio	Antioxidant effects	Choi et al.	2004
Brain injury	50 mg/kg, intraperitoneal, immediately after ischemia	Reduced neuronal damage	Reduction of matrix metalloproinase-9 activity	Park et al.	2010
Brain injury	40 mg/kg, intraperitoneal, once daily for three consecutive days prior to surgery	Reduced neuronal damage	Activation of nuclear erythroid 2-related factor 2 /antioxidant response element signaling	Han et al.	2014
Brain injury	50 mg/kg, intraperitoneal, immediately after surgery and once daily till day 7	Promoted angiogenesis	Up-regulation of the nuclear erythroid 2-related factor 2 signaling pathway	Bai et al.	2017
Brain injury	50 mg/kg, intraperitoneal, immediately after ischemia	Modulated inflammatory responses	Amelioration of tumor necrosis factor alpha, interleukin-1 beta, interleukin-6, nuclear factor kappa B /p65, cyclooxygenase-2, inducible nitric oxide synthase	Zhang et al.	2015
Brain injury	50 mg/kg, daily for 1 day and 1 h before ischemia	Reduced nitric oxide synthase and inducible nitric oxide synthase, increased endothelial nitric oxide synthase, preserved complex I–V	Complex signal transduction mechanisms	Sutherland et al.	2005
Brain injury	Consuming 0.1% (*w*/*v*) epigallocatechin-3-gallate drinking water ad libitum before and after traumatic injury	Increased neural stem cells number around the damaged area	Antioxidant and antiapoptotic activities	Itoh et al.	2011, 2013, 2012
Brain injury	100 mg/kg, intraperitoneal, after traumatic injury	Reduced interleukin-1 beta and tumor necrosis factor alpha mRNA expression, inhibited astrocyte expressing aquaporin-4 and glial fibrillary acidic protein, elevated superoxide dismutase and glutathione peroxidase activities, decreased nicotinamide adenine dinucleotide phosphate oxidase activation	Inhibition of inflammation and oxidative stress	Zhang et al.	2015

TABLE 3 Neuroprotective effects of epigallocatechin-3-gallate against other neurological disorders—cont'd

Model of injury	Treatment schedule	Finding	Possible mechanism	Author	Year
Nerve injury	25 mg/kg, injected daily for 5 days and 2 mg/kg orally daily afterwards	Increased density of retinal ganglion cells	Up-regulation of neurofilament triplet L protein expression	Ahadi et al.	Xie 2010
Nerve injury	25 mg/kg, intraperitoneal or orally, daily for 5 days and 2 mg/kg orally daily afterwards	Enhanced motor neuron survival time	Attenuation of nicotinamide adenine dinucleotide phosphate-diaphorase-d/neuronal nitric oxide synthase	Wei et al.	2011
Nerve injury	1 mg/kg, intrathecal, once daily from 1 day before to 3 days after chronic constriction injury	Decreased chronic neuropathic pain	Down-regulation of Toll-like receptor 4, nuclear factor kappa B, high-mobility group box 1 protein, tumor necrosis factor alpha and interleukin-1 beta protein expression	Kuang et al.	2012
Nerve injury	50 mg/kg, intraperitoneal, following rat sciatic nerve crush injury	Enhanced functional recovery and accelerated nerve regeneration	Down-regulation of apoptosis related genes, up-regulation of survivin gene, and up-regulation of glutathione reductase	Renno et al.	2017, 2015
Nerve injury	50 mg/kg, intraperitoneal, starting 1 h after sciatic nerve crush injury	Modulated brain-derived neurotrophic factor, glial cell line-derived neurotrophic factor and neurotrophin-3 and their receptors tropomyosin receptor kinase B, tropomyosin receptor kinase C, and nerve growth factor receptor p75	Up-regulation of neurotrophic factors and their receptors	Renno et al.	2016
Nerve injury	50 mg/kg, intraperitoneal, 1 h after nerve transaction and followed for 3 days	Reduced neural apoptosis	Modulation of malodialdehyde levels, catalase and superoxide dismutase activities, and Caspase3 and cyclooxygenase-2 expression	Kian et al.	2019
Alzheimer's disease	20 mg/kg, intraperitoneal, daily for 60 days	Effective prophylaxis for Alzheimer's disease	Modulation of amyloid precursor protein cleavage and cerebral amyloidosis	Rezai-Zadeh et al.	2005
Neurodegenerative disease	2 or 6 mg/day for 4 weeks, intragastrically	Improved degenerative changes of the brain	Modulation of beta-amyloid and amyloid precursor protein	He et al.	2012

TABLE 3 Neuroprotective effects of epigallocatechin-3-gallate against other neurological disorders—cont'd

Model of injury	Treatment schedule	Finding	Possible mechanism	Author	Year
Neurodegenerative disease	2 mg/kg/day for 4 weeks, intragastrically	Ameliorated learning and memory deficits	Modulation of TrkA/$p75^{NTR}$ signaling and apoptosis	Liu et al.	2014
Parkinson's disease	No available	Alleviated dopaminergic neuronal injury in Parkinson's disease	Inhibition of nitric oxide and tumor necrosis factor alpha	Li et al.	2004
Parkinson's disease	25 mg/kg, oral administration for 7 days	Neurorescue effects in Parkinson's disease	Regulation of the iron-export protein ferroportin and reduction of oxidative stress	Xu et al.	2017
Neurodegenerative disease	300 μg, oral gavage twice daily	Delayed disease onset, induced regeneration of hippocampal axons	Reduction of the inflammatory infiltrates	Herges et al.	2011

A summary of in vivo studies on the neuroprotective effects of epigallocatechin-3-gallate against other neurological disorders, along with treatment schedules, findings, and related molecular mechanisms, is presented in this table.

Recently, we found that EGCG protects sensory and motor neurons through attenuation of COX-2 and caspase-3, and elevation of SOD and CAT activities in rat sciatic nerve transaction model (Kian, Khalatbary, Ahmadvand, Karimpour Malekshah, & Shams, 2019).

In regard to neurodegenerative diseases, research on Alzheimer's disease (AD) revealed that EGCG treatment in Alzheimer transgenic mice reduces cerebral amyloidosis and modulates amyloid precursor protein (APP) cleavage (Rezai-Zadeh et al., 2005). Some existing evidence suggests that the EGCG's neuroprotection against Aβ-induced cell death is somewhat due to phosphatidylinositol 3-kinase (PI3K)/protein kinase B (AKT) transduction signaling and alpha-7 nicotinic acetylcholine receptor (α7nAChR) activity (Zhang et al., 2014). Liu et al. (2014) documented that EGCG through modulating the balance of TrkA/p75NTR signaling in APP/PSI transgenic mice ameliorated memory and learning deficits. Results of a study supported that EGCG in Parkinson's disease (PD) can be a therapeutic approach to alleviate microglia-mediated dopaminergic neuronal injury (Li et al., 2004). Recently the neurorescue effects of EGCG have been proven in a mouse model of PD assessed with behavioral and neurotransmitter analysis (Xu et al., 2017). Also, results of another study indicated that combination therapy of glatiramer acetate and EGCG can be a safe and promising approach for multiple sclerosis (Herges et al., 2011).

Conclusion

In recent years, dietary polyphenols have attracted a lot of attention due to their interesting biological activities. An expanding body of results obtained by pre-clinical in vitro and in vivo studies on the use of EGCG as a therapeutic option for SCI confirmed its neuroprotective properties. These beneficial effects have been mainly attributed to free radical scavenging or anti-oxidant, anti-inflammatory, and anti-apoptotic properties of EGCG. The evidence presented in this review suggests the potential of EGCG in both preventive and therapeutic usages for a variety of SCI models. At the same time, there is a lot of evidence that this natural polyphenol has proper absorption and crosses the BBB with minimal side effects. Of course, considering that no study has been conducted on the neuroprotective effects of EGCG following SCI in human, the design of clinical trials are required regarding EGCG's neuroprotection and its possible mechanisms as well as determining the dose and course of treatment remain to be explored following SCI.

Mini-dictionary of terms

- Catechins: They are natural polyphenol compounds with potent anti-oxidant activity harvested from a variety of sources.
- Free radical scavenging: Inactivation of free radicals in a biological system.

- Endogenous anti-oxidants: They are products of the body's metabolism which act as free radical scavengers.
- Synergistic effects: An effect arising between two or more substances that create a greater effect than the sum of their individual effects.
- Motor deficit index: Evaluation of neurological function with scoring of the placing/stepping reflex and ambulation.
- Intrathecal administration: Injection of therapeutic agents into the spinal sub-arachnoid space.
- Neuritogenesis: A complex phenomenon involving multiple interactions between the extracellular matrix and growing neurite.

Key facts of EGCG

- EGCG has anti-oxidant, anti-inflammatory, and anti-apoptotic properties.
- EGCG is able to cross the BBB and can reach to injured nervous tissue even at a very low concentration.
- Several experimental studies have shown that EGCG can afford neuroprotection against brain and SCIs, neurodegenerative diseases, and peripheral nerve injuries.
- The behavioral, biochemical, and histopathological evidences demonstrated EGCG treatment has protective effects against experimental model of SCI.
- The neuroprotective effects of EGCG are dose-dependent and therefore it is necessary to determine the appropriate dose.

Summary points

- Epigallocatechin-3-gallate is thought to be responsible for the most biological activities of green tea catechins, including anti-oxidant, anti-inflammatory, and anti-apoptotic properties.
- Epigallocatechin-3-gallate has been shown to be some of the neuroprotective effects against injury to the peripheral and central nervous system.
- Treatment of SCI with epigallocatechin-3-gallate improves neurological function and decreases spinal tissue loss.
- Neuroprotective effects of epigallocatechin-3-gallate against SCI are largely due to its anti-inflammatory, anti-apoptotic, and anti-oxidant properties.
- This paper summarizes current knowledge on neuroprotective effects of epigallocatechin-3-gallate and their molecular mechanisms responsible for the neuroprotection following SCI.

Chapter 35

Vitamin D and spinal cord injury

Kelly Pritchett, Brianna Rice, and Sophia Berg

Department of Health Sciences, College of Education and Professional Studies, Central Washington University, Ellensburg, WA, United States

Abbreviations

25(OH)D	25-hydroxyvitamin D, also known as calcidiol
1,25(OH)$_2$D	1,25-dihydroxyvitamin D, also known as calcitriol
IOM	Institute of Medicine
UVB	ultraviolet B
SCI	spinal cord injury
VDR	vitamin D receptor

Introduction

Based on data collected from the National Health and Nutrition Examination Survey (NHANES), the prevalence of vitamin D deficiency (<50 nmol/L) in the United States is estimated to be 39.9% (Parva et al., 2018). Historically, vitamin D is known for its role in supporting bone health and preventing osteoporosis (Jin, 2018; Laird, Ward, McSorley, Strain, & Wallace, 2010). However, vitamin D is also important for various functions in the body including immunity, cell growth, and neuromuscular function (Flueck, Hartmann, Strupler, & Perret, 2016). The discovery of vitamin D receptors in skeletal muscle tissue has led to an increase in research examining vitamin D and its potential effects on exercise performance. Active individuals with spinal cord injury (SCI) have been suggested to be at an increased risk for vitamin D insufficiency and deficiency due to low dietary intake of foods high in vitamin D (Gerrish et al., 2017), anticonvulsant medications which interfere with vitamin D metabolism (Gröber & Kisters, 2012), and lifestyle factors such as reduced exposure to sunlight (Flueck & Perret, 2017; Pritchett, Pritchett, Stark, Broad, & LaCroix, 2019). Thus, a sufficient vitamin D (>75 nmol/L) status is dependent on diet, location of residence, skin pigmentation, time spent outdoors and whether an individual wears sunscreen or sun protective clothing (Flueck & Perret, 2017; Pritchett et al., 2016). Research has suggested that dietary intake for both micronutrients and macronutrients are insufficient in the para-athlete population (Scaramella, Kirihennedige, & Broad, 2018).

Vitamin D recommendations: Intake, sources, and status

Vitamin D, also referred to as calciferol, is a fat-soluble vitamin that acts like a prohormone. Vitamin D can be obtained from sun exposure, supplements, and foods like fatty fish, beef liver, eggs, mushrooms, and fortified foods (see Table 1), which are the main source of dietary vitamin D in American diets (National Institutes of Health [NIH], 2020).

While there are several forms (vitamers) of vitamin D, two major forms include cholecalciferol (D_3) and ergosterol (D_2). Ergosterol is added to foods to fortification purposes (i.e., cereal), and it naturally present in fungi like mushrooms. Vitamin D_3 is synthesized in the skin as well as consumed in the diet through animal sources (Ross, Taylor, Yaktine, & Valle, 2011). When exposed to ultraviolet B (UVB) radiation, 7-dehydrocholesterol (7-DHC) is converted into previtamin D_3, and later converted vitamin D (Hossein-nezhad & Holick, 2013) (Fig. 1).

This type of synthesis is influenced by variables like skin exposure, season, and location of residence. There are seasonal variations in vitamin D synthesis for individuals greater than 35 to 37 degrees N latitude during the winter due to the unavailability of UVB radiation during winter months in these locations. Excessive pollution and cloud cover are also variables that can impact the ability to synthesize vitamin D through UVB radiation (Cannell, Hollis, Sorenson, Taft, & Anderson, 2009). Other variables that affect the ability to synthesize vitamin D via sunlight are sunscreen and clothing choice. Recent research suggests that sunscreen use may not play a large role in low 25(OH)D status when using moderate sun protection

TABLE 1 Dietary sources of vitamin.

Food	Standard Portion	Approximate Vitamin D Content (IU)
Fortified foods		
Milk, low fat	1 cup	117
Soy beverage (soy milk)	1 cup	119
Yogurt, low fat	8 oz	116
Cheese, American	1.5 oz	85
Orange juice	1 cup	100
Nonfortified foods		
Salmon (various)	3 oz	383–570
Rainbow trout, freshwater	3 oz	645
Light tuna, canned	3 oz	231
Mushrooms (various	1 cup	114–110
Eggs	1 egg	37
Beef liver	3 oz	42

factor (SPF). Currently, research has not examined the use of high SPF sunscreens and the effect they may have on 25(OH)D concentrations (Neale et al., 2019). Protective clothing as well as increased indoor activity does decrease skin exposure to the sun which may negatively impact 25(OH)D status. Individuals that have dark pigmented skin are at higher risk for vitamin D deficiency as well since darker skin pigmentation requires more sun exposure to absorb the same amount of UVB radiation as someone with lighter skin pigmentation (Holick & Chen, 2008). Fig. 2 displays risk factors for low 25(OH)D status.

Whether synthesized in the skin or ingested through foods and supplements, vitamin D is hydroxylated by the liver into the major circulating form of vitamin D, 25(OH)D, which is the form of vitamin D measured to assess vitamin D status (Hossein-nezhad & Holick, 2013). 25(OH)D is further hydroxylated in the kidneys to form $1,25(OH)_2D$ Vitamin D, which is the biologically active form of vitamin D, performing many functions in the body related to its interactions with vitamin D receptors (VDR) (Hossein-nezhad & Holick, 2013). Vitamin D that has been synthesized by the sun stays in circulation two to three times longer than vitamin D that is taken in supplement form. This is because vitamin D taken in supplement form is partially bound to lipoproteins which is cleared from the system before being absorbed (Wacker & Holick, 2013). Since vitamin D is a fat-soluble vitamin, there is research showing an inverse relationship between adiposity and low vitamin D status, which puts those who are obese at greater risk for vitamin D deficiency (Larson-Meyer & Willis, 2010; Ogan & Pritchett, 2013).

The recommended intakes of vitamin D from the Institutes of Medicine (IOM) and Endocrine Society are noted in Table 2. The IOM guidelines are created from a population model aiming to prevent vitamin D deficiency in most of the population (Hossein-nezhad & Holick, 2013). IOM notes that most of the population intakes enough vitamin D to reach "sufficient" serum 25(OH)D levels (20 ng/mL) (Hossein-nezhad & Holick, 2013). Guidelines from the Endocrine Society recommend higher intakes of vitamin D, as it is based from a medical model that incorporates the wide array of vitamin D functions, and suggests 30 ng/mL 25(OH)D levels are beneficial, and that there is a higher upper limit than IOM suggests (Hossein-nezhad & Holick, 2013).

25(OH)D status can be measured in either nanograms (ng/mL) or in nanomoles (nmol/L). The World Health Organization and Endocrine Society considers a vitamin D deficiency as <50 nmol/L (<20 ng/ml), insufficiency as 50 to 75 nmol/L (25–30 ng/mL) and a sufficient status would be >75 nmol/L (>30 ng/mL) (Holick et al., 2011). The best indicator of vitamin D status is a serum concentration of 25(OH)D according to the National Institute of Health due to its 15-day half-life (National Institutes of Health, 2020). $1,25(OH)_2D$ concentration, on the other hand, is not a good indicator of vitamin D status since concentrations are constantly changing related to metabolic processes (National Institutes of Health, 2020).

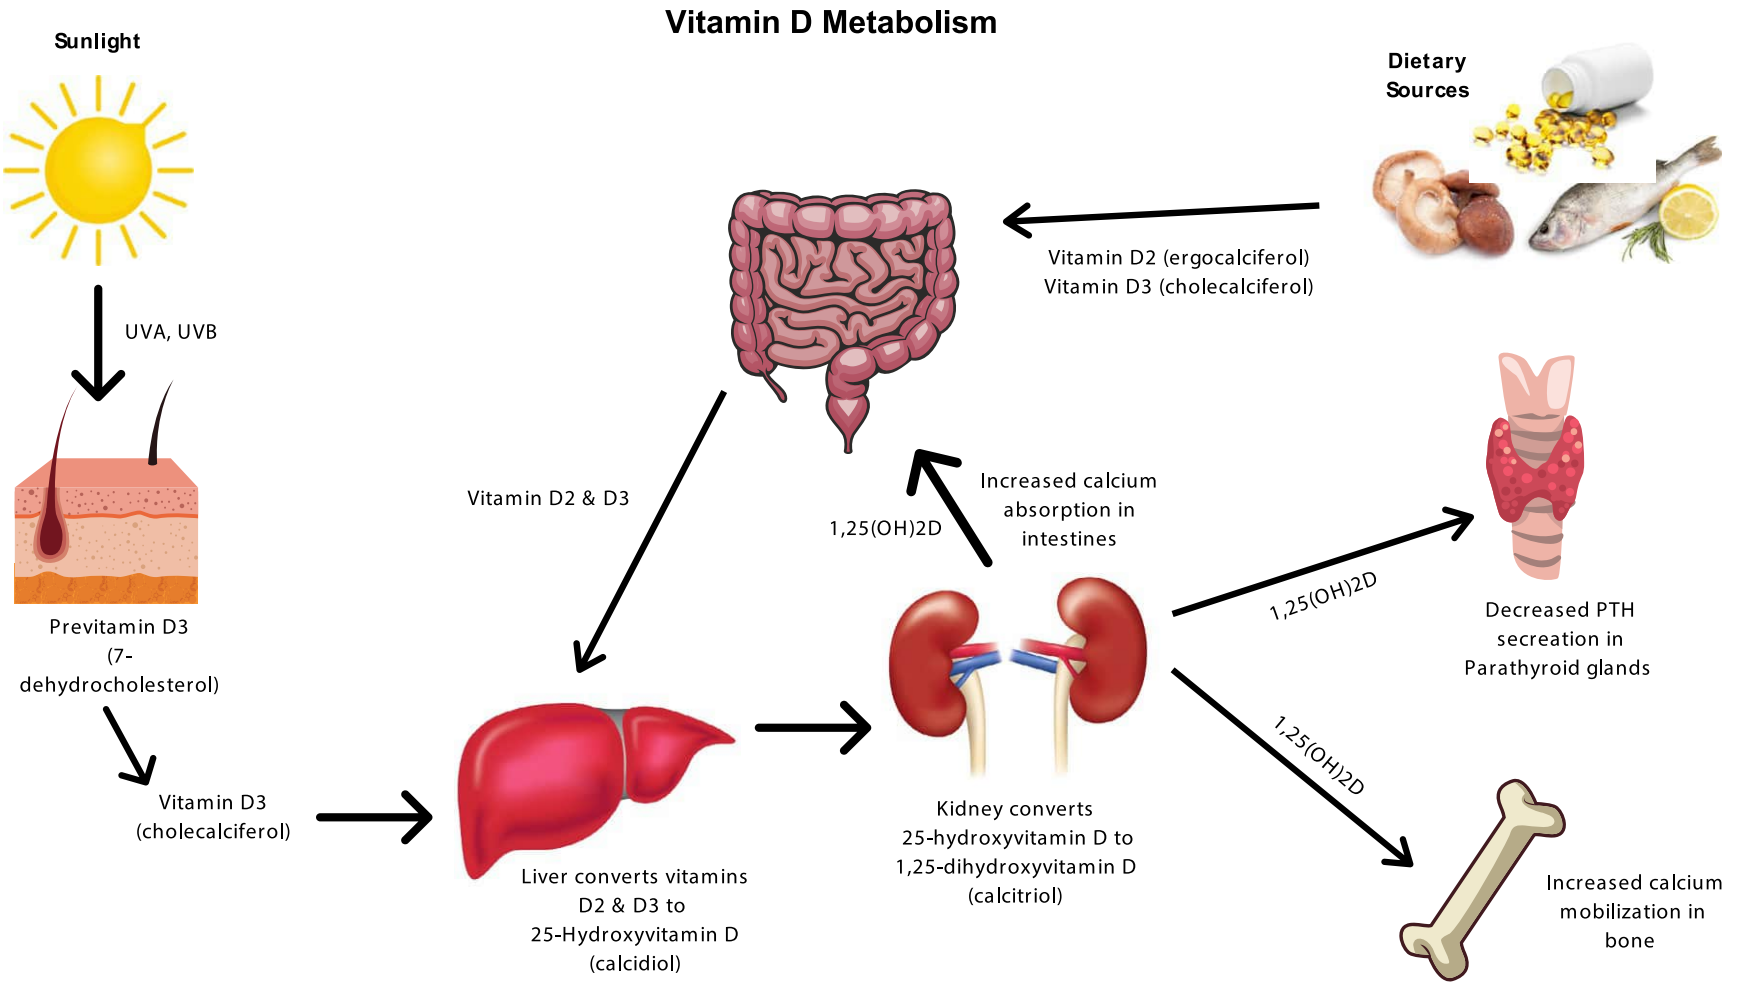

FIG. 1 Vitamin D metabolism.

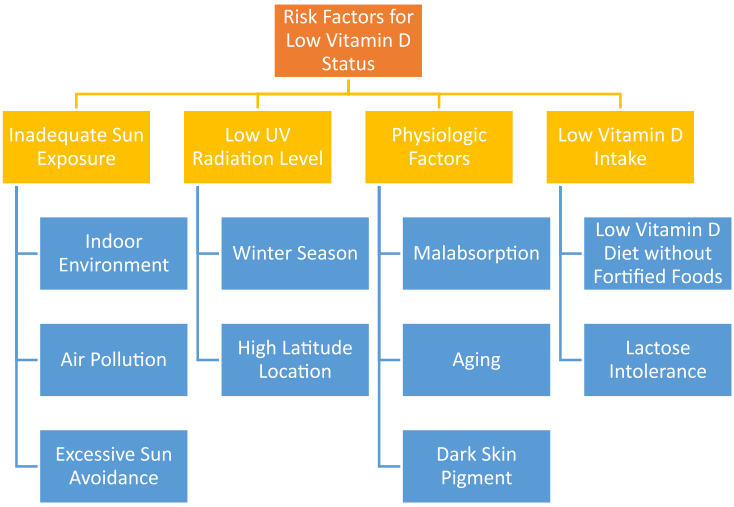

FIG. 2 Risk factors for insufficient/deficient 25(OH)D status.

TABLE 2 Recommended Intake and Upper Limit for Vitamin D.

Age	Recommended Intake (IU/day)	Upper Limit (IU/day)
National Institute of Medicine		
Children (0–18 years)	400–600	2500 (1–3 years) 3000 (4–8 years) 4000 (13–18 years)
Adults (19–70 years)	600	4000
Older Adults (>70 years)	800	4000
Pregnancy/Lactation	600	4000

Table from Ogan, D., & Pritchett, K. (2013). Vitamin D and the athlete: Risks, recommendations, and benefits. *Nutrients, 5* (6), 1856–1868. doi:10.3390/nu5061856.

Function and physiology

Vitamin D plays an important role in many different functions of the body, including immunity, bone health, muscle and neuromuscular function, hormone synthesis, cell development, and gene expression. Vitamin D has also been linked to a reduction in cancer risk, autoimmune disorders, and chronic disease (Ross et al., 2011).

Bone health

Vitamin D is known for its role in bone health and prevention of osteoporosis. Vitamin D is vital to the transcription of calbindin, a carrier protein present in enterocytes which aids in the absorption of calcium, the most abundant mineral in bones. Vitamin D is also involved in the regulation of serum calcium and phosphorus, which is important to the processes of bone mineralization and contraction of muscles (National Institutes of Health, 2020). In athletes, vitamin D status is important to consider for bone health and preventing fractures (Ogan & Pritchett, 2013). Lappe et al. (2008) provided 2000 mg of calcium and 800 IU of vitamin D to a group of female Navy recruits while the other group received a placebo for 8 weeks. The supplement group had a 20% lower prevalence of stress fractures than the placebo group (Lappe et al., 2008).

Muscle function

Vitamin D receptors (VDR) have been identified in nearly every type of cell in the body, including muscle cells (Ogan & Pritchett, 2013). The VDR has either a positive or negative response after being bound with vitamin D which targets gene expression, and therefore may play a large role in regulating skeletal muscle tissue (Ogan & Pritchett, 2013; Tanner & Harwell, 2015). Vitamin D may also affect muscle contractions by influencing calcium levels in the sarcoplasmic reticulum of muscles through alteration in the quantity and/or efficiency of calcium binding sites (Ogan & Pritchett, 2013). In addition to associations found between vitamin D status and muscle weakness, pain, and balance, research has also suggested that vitamin D plays a role in fast twitch muscle fiber morphology. It has been suggested that with an increase in vitamin D status from deficient to sufficient, fast twitch muscle fiber size and number will increase (Cannell et al., 2009; Girgis, Clifton-Bligh, Hamrick, Holick, & Gunton, 2013). However, further research is needed to determine the role of vitamin D in muscle fiber morphology.

Extraskeletal functions

Adequate vitamin D status has been associated with decreased risk of certain cancers, autoimmune disorders, infectious disease, mental disorders, cardiovascular disease, and Type 2 diabetes (Hossein-nezhad & Holick, 2013). Vitamin D can work as an immune modulator, mainly through interactions with receptors and affecting T-cell differentiation (Hossein-nezhad & Holick, 2013). Vitamin D may decrease risk of cardiovascular disease through action in the regulation of the renin-angiotensin-aldosterone system and inflammatory pathways, although clinical trials in this area have not been conclusive (National Institutes of Health, 2020). Vitamin D is involved in neurological function, as VDRs are present on neurons and glia (National Institutes of Health, 2020). VDRs are also present on pancreatic beta cells, and may be involved in insulin signaling, glucose control, and reducing inflammation, thereby possibly decreasing risk of Type 2 diabetes, although more research is needed in this area (National Institutes of Health, 2020).

Vitamin D status of active individuals with SCI

The vitamin D status of active individuals has become a popular area of study over the past decade. Athletes are potentially at an increased risk for vitamin D deficiency due to the increased enzymatic activity that occurs during exercise (Dahlquist, Dieter, & Koehle, 2015). Many studies have found that athletes are at an increased risk for 25(OH)D deficiency during the winter months and that athletes participating in an indoor sport have a higher rate of than those that play an outdoor sport (Cannell et al., 2009; Close et al., 2013; Fields, Payne, Gallo, Busteed, & Jones, 2019; Halliday et al., 2011; Krzywanski et al., 2016; Larson-Meyer & Willis, 2010; Ogan & Pritchett, 2013; Owens, Allison, & Close, 2018; Wiciński et al., 2019).

Recently, research has examined the vitamin D status of athletes with a physical impairment. This includes athletes with SCI, amputations, cerebral palsy, and other impairments as well. Athletes with SCI may be at higher risk for vitamin D deficiency due to a lack of mobility and thermoregulatory dysfunction. Athletes with SCI may also have additional malabsorption concerns due to taking anticonvulsant medications (Flueck, Schlaepfer, & Perret, 2016; Krempien & Barr, 2011; Oleson, Patel, & Wuermser, 2010; Pritchett et al., 2016). These aspects decrease the amount of time that individuals with SCI spend outside, thus decreasing the ability to synthesize vitamin D by sunlight (Flueck & Perret, 2017). It is important for active individuals with SCI to get adequate vitamin D as it is important for bone health.

Krempien and Barr (2011) examined the nutrient intake of elite Canadian athletes with SCI (Krempien & Barr, 2011). This study used self-reported food diaries to assess diet and found energy and micronutrient intake, including vitamin D, to be lower than recommended. Scaramella and colleagues further highlighted that para-athletes are at an increased for carbohydrate, iron, protein, and vitamin D deficiencies (Scaramella et al., 2018).

Studies have also focused on 25(OH)D status related to lifestyle factors in athletes with SCI. These lifestyle factors include diet, place of residence, and skin color. Other factors that are important for determining 25(OH)D status in athletes with SCI are whether they play an indoor or outdoor sport, medication use that may inhibit vitamin D absorption and limited time outdoors due to impaired thermoregulation (Pritchett et al., 2016).

Multiple studies have found that athletes with SCI are at greater risk for vitamin D status. Oleson et al. (2010) found that 96.4% of participants with chronic SCI had an insufficient 25(OH)D status during the winter months, and 81% were insufficient during the summer months (Oleson et al., 2010). This was further supported by another study in Swiss wheelchair athletes that compared 25(OH)D status between winter and summer months, and as indoor versus outdoor athletes. Flueck et al. found that vitamin D insufficiency was more prevalent in athletes during winter months and in athletes that played indoor sports (Flueck, Hartmann, et al., 2016; Flueck, Schlaepfer, & Perret, 2016).

An observational study in athletes from the Canadian Wheelchair Sports Association and the US Olympic Committee Paralympic program was conducted to examine the effects of lifestyle factors on 25(OH)D status during the autumn and winter months (Pritchett et al., 2016). There was no significant difference found in vitamin D status between autumn and winter, with 41% to 51% of athletes having an insufficient and 15.4% having a deficient vitamin D status. Time spent outside was significantly correlated with vitamin D status in the autumn, but not during the winter. Furthermore, a seasonal decline in vitamin D status was not observed regardless that athlete sun exposure decreased from autumn to winter. In this study, a greater percentage of athletes that competed in indoor sports were deficient compared to those that played outdoor sports (Pritchett et al., 2016). Thus, research is needed to identify the optimal 25(OH)D levels for active individuals with SCI.

Vitamin D and athletic performance in athletes with SCI

There have been conflicting results in the literature as to whether vitamin D provides an ergogenic benefit for exercise performance and recovery in active individuals. Flueck et al. examined the effects of vitamin D supplementation in athletes with a chronic SCI on 25(OH)D status and whether it would subsequently impact performance (Flueck, Schlaepfer, & Perret, 2016). Twenty indoor elite wheelchair athletes received 6000 IU of vitamin D_3 over a 12-week period. After 6 weeks of supplementation, vitamin D status increased significantly and reached an optimal level in all athletes. However, there was no significant difference found for any performance measurements except for isokinetic strength in the nondominant hand, although this result may have been influenced by training. In order to truly test whether the neuromuscular changes were due to vitamin D supplementation or a change in 25(OH)D status, a placebo group is needed (Flueck, Schlaepfer, & Perret, 2016).

Another study examined the efficacy of a 12- to 16-week sliding scale vitamin D supplementation protocol on 25(OH)D status and performance measures (handgrip strength, and 20-m wheelchair spring) in elite Paralympic athletes (Pritchett et Al., 2019). Participants with sufficient 25(OH)D status received a maintenance dose (15,000 IU/week of vitamin D), insufficient participants received 35,000 IU/week for 4 weeks and then received the maintenance dose, and participants that were deficient received 50,000 IU/week of vitamin D for 8 weeks and then received the maintenance dose. Mean 25(OH)D status significantly increased after supplementation (66.3 ± 24.3 nmol/mL presupplementation; 111.3 ± 30.8 nmol/mL postsupplementation). There were no significant differences in 20 m wheelchair sprints or handgrip strength; however, 62% of participants did improve handgrip strength.

Conclusion

Further research is warranted in a number of areas surrounding athletic populations, especially athletes with SCI. Recommendations for optimal vitamin D status for the para-populations need to be addressed as this population can be more susceptible to deficiency. Based on previous findings, athletes with SCI should be screened biannually for 25(OH)D status to determine whether supplementation is needed. A 12- to 16-week sliding scale supplementation protocol based on the individual's vitamin D status can be applied for individuals with an insufficient or deficient status. Furthermore, the relationship between athletic performance and vitamin D status remains unclear and there is a need for more research in this area.

Application to other areas of neuroscience (200–750 words)

This chapter reviewed vitamin D status, functions, and physiology. Vitamin D is important for various functions in the body including immunity, cell growth, and neuromuscular function. The discovery of vitamin D receptors in skeletal muscle tissue has led to an increase in research examining vitamin D and its potential effects on exercise performance. Current research suggests that active individuals with SCI are vulnerable populations with an increased risk for vitamin D deficiency. Active individuals with SCI present unique challenges in terms of nutritional needs, including vitamin D status. Thus, it is important that active individuals with SCI to obtain adequate vitamin D as it is important for bone health. It is suggested that active individuals with SCI may be a at higher risk for vitamin D deficiency due to a lack of mobility, thermoregulatory challenges, and malabsorption concerns due to taking anticonvulsant medications. These aspects decrease the amount of time that individuals with SCI spend outside, thus decreasing the ability to synthesize vitamin D by sunlight. Given that the diet does not supply enough vitamin D, active individuals with SCI may need vitamin D supplementation to obtain optimal vitamin D levels. Active individuals with SCI should receive specific and appropriate nutrition assessments and interventions, according to their needs.

Mini-dictionary of terms

Vitamin D—the fat-soluble vitamin available in food and from the sun.

Cholecalciferol—or vitamin D_3, the form of vitamin D found in the skin when exposed to sunlight, and the preferred form found in supplements.

Ergocalciferol—or vitamin D_2 found in supplements and in mushrooms and fungi in the diet.

Vitamers—various forms of vitamins that have a similar physiological activity in the body (i.e., cholecalciferol, and ergocalciferol).

Calcitriol—(1,25 hydroxyvitamin D_3) the active from of vitamin by made by the kidney but used to treat low calcium in individuals with chronic kidney disease or decreased function of the parathyroid glands.

Key facts of vitamin D and spinal cord injury

- Vitamin D is known for its role in bone health and prevention of osteoporosis.
- Vitamin D deficiency (<50 nmol/L) prevalence in the United States is estimated to be 39.9%
- Vitamin D status is assessed by serum 25(OH)D concentration
- Vitamin D can be obtained from sun exposure, foods, and supplements.
- Rickets was one of the first discovered conditions associated with a vitamin D deficiency.

Summary points

- Vitamin D is important for skeletal, muscle, immune, and neurological health.
- Athletes are at higher risk for vitamin D deficiency, related to increased enzymatic activity during exercise and indoor sports.
- Athletes with SCI may be a at higher risk for vitamin D deficiency due to a lack of mobility, thermoregulatory dysfunction, and malabsorption concerns due to taking anticonvulsant medications.
- Active individuals with SCI should be screened biannually for 25(OH)D status to determine whether supplementation is needed.

Abbreviations

A	adult
C	cervical
ChABC	chondroitinase ABC
CNS	central nervous system
CSPG	chondroitin sulfate proteoglycans
CST	corticospinal tract
E	embryonic
Htt	huntingtin gene
KLF	Krüppel-like factor
MSE	motor synergy encoder
mTOR	mammalian target of rapamycin
NgR	Nogo-A receptor
NPC	neural progenitor cell
NT-3	neurotrophine-3
P	post-natal
PTEN	tumor suppressor phosphatase and tensin homolog
SCI	spinal cord injury
SOCS3	suppressor of cytokine signaling 3
T	thoracic
YA	young adult

Introduction

The corticospinal tract (CST) is an axonal bundle that starts from cortical layer V pyramid neurons and travels through brain and brainstem to terminate in spinal cord. One major characteristics of CST is that the majority of the CST axons cross the midline at the pyramidal decussation, resulting the right side of brain to control the left side of the body and vice versa. The location of CST is different among different species, from ventral dorsal column in rodent to dorsal lateral funiculus in cat, non-human primate, and human (Welniarz, Dusart, & Roze, 2017). In addition, the CST termination is different among different species, from dorsal to ventral gray matter.

The main function of the CST is to control primary motor activity of the body, especially the voluntary movements. Disruption of CST along with other tracts after spinal cord injury (SCI) definitely interferes with communication between brain and the spinal cord below the injury, resulting in loss of motor, sensory, and autonomic function. Although studies show that CST sprouts after SCI from uninjured or injured axons, especially after genetically manipulation and therapeutic treatments (Blackmore et al., 2012; García-Alías, Barkhuysen, Buckle, & Fawcett, 2009; Liu et al., 2010; Rosenzweig et al., 2019), true regeneration from transected CST is rarely reported until recently from our lab (Kadoya et al., 2016).

Diagnosis and Treatment of Spinal Cord Injury. https://doi.org/10.1016/B978-0-12-822498-4.00036-1

Regeneration of CST, including sprouting and regenerative sprouting of CST, is vitally important to restore motor function, especially the voluntary skilled motor function, after SCI.

In this chapter, we will review development of CST and its innervation of spinal cord neurons. In addition, we will review injury-induced CST sprouting, and genetical manipulation and therapeutic treatment to promote CST sprouting and regenerative sprouting. Finally, we will discuss our own work for promotion of CST regeneration by transplantation of caudalized neural progenitor cells (NPCs) after SCI.

CST development

CST outgrowth

The corticospinal tract (CST) is a motor pathway in central nervous system (CNS) starting from the cerebral cortex, traveling through internal capsule and brainstem, most of them crossing the midline at the pyramidal decussation, and ending at the spinal cord (Welniarz et al., 2017). In the popular rodent model of CNS development, CST axons reach brainstem at embryonic day 17 (E17), caudal medulla at E19, and cross the middle line and enter the spinal cord around post-natal day 0 (P0). CST axons continue to extend into entire spinal cord, including cervical cord around P1–2, thoracic around P3, and lumbar around P5–7 (Fig. 1) (Joosten et al., 1989; Welniarz et al., 2017). The development of CST in primate most occurs before birth. For example, CST reaches the entire spinal cord at birth in non-human primate (Welniarz et al., 2017) and reach the entire cervical spinal cord at 24 weeks post-conceptional age in human (Eyre, 2003). The growth of CST is leaded by a small number of "pioneer" axons followed by other axons that eventually populated the CST tract (Joosten et al., 1989). Following the outgrowth of CST, myelination starts around P10 and finishes in the entire spinal cord around 4 weeks in rodent spinal cord (Fig. 1), indicating readiness for electro impulse transmission (Joosten et al., 1989).

CST location and termination pattern in spinal cord

CST travels in the spinal cord white matter, which just likes other descending systems in the spinal cord. However, the location where CST travels in the spinal cord varies among species (Welniarz et al., 2017). While the crossed main CST locates in the most ventral portion of dorsal column in rodent, it shifts to dorsal lateral funiculus in cat and primates, including human (Fig. 2). The small proportion of uncrossed lateral and ventral CST are in similar location among different species. In addition, the termination pattern of CST into spinal cord gray matter is different among species. In rodent, the CST terminates most in dorsal and intermediate zone, but not directly into motor neurons in the ventral horn (Fig. 2A). However, in primates, both crossed main CST tract and uncrossed CST shift their termination ventrally into intermediate zone and ventral horn (Fig. 2C and D), indicating direct cortico-motoneuronal connections (Welniarz et al., 2017).

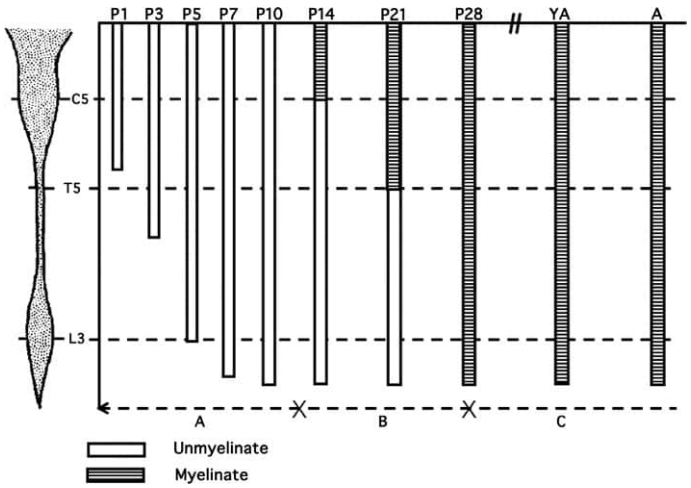

FIG. 1 Corticospinal tract outgrowth, myelination, and maturation. CST outgrowth (A) from post-natal day 1 (P1) to P10, myelination (B) from P10 to P24, and maturation (C) in young adult (YA) and adult (A) spinal cord in rats. *Adopted and redrawn from Joosten, E. A., Gribnau, A. A., & Dederen, P. J. (1989). Postnatal development of the corticospinal tract in the rat. An ultrastructural anterograde HRP study*. FIG. 2 Location and termination pattern of crossed and uncrossed CST in the spinal cord in mammals. (A) Rodent; (B) cat; (C) monkey; and (D) human. *Reproduced from Welniarz, Q., Dusart, I., & Roze, E. (2017). The corticospinal tract: Evolution, development, and human disorders.* Developmental Neurobiology, 77*, 810–829 with permission.*

Furthermore, our own work demonstrates additional extensive decussation and bilateral termination of CST in cervical region in monkey, nearly twice as many CST axons decussating in the cervical midline (Rosenzweig et al., 2009).

Precise control of skilled motor functions by defined CST populations

A recent study identifies spatially defined CST populations with distinct spinal projections that control different musculature groups and function in skilled forelimb motor function in mice (Wang et al., 2017). They reveal a sequential

activation of topographically organized CST neurons during skilled forelimb performance using in vivo calcium imaging with intersectional approach to specifically label and monitor different regions of CST neurons. Manipulation of region-specific CST neurons by ablation of specific population with diphtheria toxin identifies that caudal forelimb area controls reaching while rostral forelimb area controls grasping. The identification of these spatially defined groups of CST neurons that controls different skilled forelimb movements enables us to understand how CST system precisely works and how to repair it after SCI.

Identification of cellular node for CST control of motor function in mice

Since CST terminate mostly in dorsal and intermediate zone in rodent, it is important to identify those segmental interneurons and propriospinal neurons that relay CST signal into motor neurons. Levine et al. (2014) identify a neuronal population term "motor synergy encoder (MSE)" in the mouse spinal cord that may function as relay neurons from CST to motor neurons for voluntary motor movement. The MSE directly receive CST inputs in addition to sensory pathways, and have monosynaptic connection to spinal motor neurons. Molecular study reveals three candidate genes, *Tfap2b*, *Satb1*, and *Satb2*, that specifically identify MSE. Identification of MSE could direct neural stem cell study to generate these MSE progenitor cells as graft to attract CST regeneration to mimic their relays for CST input into spinal cord motor neurons below SCI.

Spinal cord injury induced spontaneous sprouting of CST

Classical work

Spontaneous sprouting of spared axons may innervate denervated targets and has been regarded as an underlying factor for functional recovery after SCI. In a classical work to investigate anatomical plasticity of CST, Kuang and Kalil (1990) unilaterally lesioned CST tracted at medullary pyramids in young hamster from age 5 to 23 days. They injected vulgaris leucoagglutinin (PHA-L) into intact side to label uninjured CST for 2 weeks. Immunohistochemical study reveals that PHA-L labeled CST sprouts into contralaterally denervated spinal cord side 4 weeks post-injury. CST sprouting is maximal in very young age of 5 days and declines with increased ages. Interestingly, the sprouted CST axons keep the same topographical specificity as normal CST arborization. Their results suggest that sprouting occurs in response to local signals which govern the specificity of denervation and induce sprouting similar to those normal development of corticospinal connections.

Dorsal injury: Ventral CST sprouting

Collateral sprouting after CNS injuries has been proposed as a key mechanism for spontaneous functional recovery. Several studies examined the mechanisms underlying recovery after lesions of motor systems in rodents, including rats and mice. After complete lesions of the main dorsal CST that comprises more than 95% of all CST axons at C3, the uninjured ventral CST spontaneously sprouts into medial motoneuron pools within cervical spinal cord, which correlates with functional recovery (Weidner, Ner, Salimi, & Tuszynski, 2001). When both dorsal and ventral CST axons are lesioned to remove almost all CST axons, functional recovery abolishes. These results indicate that extensive spontaneous structural plasticity of CST is a mechanism underneath the motor functional recovery after SCI.

Dorsal column injury: Dorsolateral CST spouting

The dorsolateral CST is dispersed throughout the dorsolateral columns. The pathways underlying dorsolateral CST spouting remain poorly understood. By performing optogenetic mapping of motor cortex after a mid-cervical dorsal column SCI that interrupts most corticospinal transmission in mice, Hilton et al. (2016) demonstrate that the motor cortex can reestablish output to the limbs longitudinally. Importantly, they dissociated for the first time the role of spared dorsolaterally projecting corticospinal neurons in mediating spontaneous recovery after SCI. They found that silencing of dorsolateral corticospinal neurons projecting caudal to the injury site by inhibitory DREADD (designer receptor exclusively activated by designer drug) was sufficient to result in the reappearance of deficits on the horizontal ladder task early after injury (Hilton et al., 2016). Their results demonstrate that spared dorsolateral CST plays an important role for spontaneous recovery of skilled locomotion in adult mice despite the limited reconstitution of corticospinal density after injury.

Unilateral hemisection: CST cross into denervated side in monkeys

Unilateral hemisection is an important SCI model to assess extensive spontaneous regeneration of adult CST axons that contribute to limited recovery after SCI. This model is especially valid in non-human primates since the main crossed CST locates in dorsolateral funiculus in each spinal cord hemisphere (Fig. 2C). To investigate mechanisms underlying spontaneous recovery after incomplete SCI, Rosenzweig et al. (2010) performed unilateral C7 spinal cord hemisections to adult rhesus monkeys and analyzed behavioral, electrophysiological and anatomical outcomes. They found enhanced spontaneous plasticity of CST axons that cross the midline from intact CST and into denervated injury site below hemisection site with 60% reconstitution of pre-lesion axon density. This extensive CST reconstitution is associated with injured forelimb functional recovery, including coordinated muscle recruitment, hand function and locomotion. This study demonstrates a very extensive CST sprouting to reconstitute injured spinal cord, which highlights the importance of primate model of SCI.

To further dissect the mechanism underlying association of CST sprouting and the forelimb functional recovery, Nakagawa, Ninomiya, Yamashita, and Takada (2015) performed C7–8 unilateral SCI in adult macaque and assessed extent of spontaneous recovery of manual dexterity using a reaching/grasping task. They found gradual recovery of the impaired dexterous manual movements. CST from uninjured hemisphere sprouts into the denervated site below injury. However, they found changes of the laminar distribution of CST axons. The sprouting CST axons preferentially innervate into spinal cord lamia IX containing the spinal motor neuron pool, indicating direct innervation of the motor neurons. On the other hand, sprouting CST axons rarely innervate the dorsal laminae. This study indicates that the reorganization of CST axons below the SCI site is an important mechanism associated with recovery of forelimb movements (Nakagawa et al., 2015).

Rewiring hindlimb CST

Large thoracic spinal cord injuries in adult rats result in disruption of hindlimb function. To assess whether the hindlimb CST can rewire after thoracic spinal cord injury, Bareyre et al. (2004) demonstrate that transected hindlimb CST axons sprout into the cervical gray matter to contact short and long propriospinal neurons (PSNs). Interestingly, long PSNs naturally innervate lumbar motor neurons, which forms a new intraspinal circuit relay that transmits the hindlimb CST input to its original lumbar spinal targets. In a follow-up study, the same group found additional CST plasticity (Ghosh et al., 2010). They found that injured hindlimb CST sprouts into cervical spinal cord after a thoracic SCI, which forms a new forelimb CST projection in the rostral part of the original hindlimb cortex. They confirm this expansion of forelimb CST in sacrifice of injured hindlimb CST by voltage-sensitive dye (VSD) imaging and blood-oxygen-level-dependent functional magnetic resonance imaging (BOLD fMRI). These studies indicate the existence of great CST plasticity and rewiring after SCI.

Promotion of CST regenerative sprouting

Promotion of CST regenerative sprouting by NT-3

Besides above reports about spontaneous sprouting of CST axons after SCI, many researchers attempt to promote further CST sprouting and regenerative sprouting that could support functional recovery using various treatments. In an early prototype study to search whether neurotrophins can enhance SCT sprouting, Schnell, Schneider, Kolbeck, Barde, and Schwab (1994) found that neurotrophine-3 (NT-3) can enhance CST sprouting first in intact post-natal rats (P2–5) just after CST extends into thoracic cord and next in young adult rats (4–7 weeks) that received low thoracic dorsal hemisection injury. Notably, the main CST is completely transected after injury, and there is no regeneration from cut axon tips into lesion site that is an empty cavity. However, CST axons sprout into ventral cord above injury site and continue to grow along the intact ventral portion of cord to reach caudal cord below injury. Combination of NT-3 single injection with an antibody that can block inhibition greatly enhance long distance of CST growth (Schnell et al., 1994).

While Schnell et al. (1994) delivered NT-3 for a single protein injection into spinal cord above injury site, which lasts short period of time, Grill, Murai, Blesch, Gage, and Tuszynski (1997) used an ex vivo gene therapy approach to deliver NT-3 by grafting of genetically modified fibroblasts expressing NT-3 into the same SCI model, low-thoracic dorsal hemisection, for continuous local supply of NT-3 in the rat SCI site. Immunohistochemistry demonstrates significant growth of CST axons at and caudal to the injury site comparing to control rats 3 months post-graft. In addition, a significant partial functional recovery on grid walking is reported, which is associated with CST regenerative sprouting. Similarly, delivery of NT-3 by this ex vivo gene therapy promotes chronically (3 months) injured CST regenerative sprouting up to 15 mm distal to SCI site (Tuszynski et al., 2003). In another study using gene therapy, a long-term NT-3 in vivo delivery to the lumbar

enlargement area through retrograde transport of NT-3 by sciatic injection of adenoviral vector expressing NT-3 promotes CST axonal growth from intact CST into injured side where injury is far rostral at medulla level (Zhou, Baumgartner, Hill-Felberg, McGowen, & Shine, 2003). These studies indicate that NT-3, especially for local and sustained delivery, support CST axonal re-growth after CST injury.

In vivo NT-3 gene delivery may not be easily translated to clinical application. A recent study implants a one-centimeter long biomaterial chitosan scaffold to slowly release NT-3 into a T8 lateral hemisection site in adult rhesus monkey (Rao et al., 2018). Antegrade labeled CST axons regenerate into scaffold and reach the caudal end while there is no regeneration of CST in lesion only control monkey. This is a true regeneration since lateral hemisection completely transects the main CST located in dorsal lateral funiculus and the CST axons grow from their cut ends (Rao et al., 2018). However, there is no empty chitosan scaffold control and no quantification of proportion of CST axon regenerated. In addition, this study shows motor and sensory functional recovery. These studies indicate that NT-3, especially for local and sustained delivery, support CST axonal re-growth after CST injury.

Promotion of CST regenerative sprouting by overcome of myelin inhibitors

While certain neurotrophins can function as chemoattractant to attract CST axon to grow, overcoming of inhibitory environment in the injured adult spinal cord could promote further growth of CST. One of the major inhibitions is myelin-associated inhibitors, such as a 35- and a 250-kd membrane proteins named NI-35 and NI-250, initially discovered by Martin Schwab's group (Sartori, Hofer, & Schwab, 2020). Afterwards they raised a monoclonal antibody, IN-1, against these two inhibitory proteins (Schnell & Schwab, 1990). CST sprouts into caudal cord through spared ventral tissue after mid-thoracic dorsal hemisection in young rats (2–6 weeks) after administration of IN-1 produced by tumors intracerebrally. Following this seminar study, various studies were conducted to demonstrate growth of CST axons after similar incomplete SCI model in adult rodent and monkey using IN-1 or its related antibodies termed anti-Nogo-A with or without other treatments, although the number of sprouting axons is very modest and most injury models are hemisection that is rare in human (Chen et al., 2017; Sartori et al., 2020; Wang et al., 2020). Nevertheless, clinical trial using Nogo-A antibody intrathecally infused continuously for 1 month for acute and severe SCI patients started as early in 2006 and finished in 2011 with certain safety data (Sartori et al., 2020). A phase II trial started 8 years later in 2019 and arrowed down to acute cervical SCI.

In addition to various IN-1 or Nogo-A antibody studies, the cloning of Nogo gene opens a new door to study its receptors for inhibitory signal transduction mechanism as well as CST regeneration in Nogo and its receptor deficient mice (Sartori et al., 2020). Although early studies report variable amount of CST regeneration in incomplete low-thoracic dorsal hemisection in Nogo mutant mice, a later study re-assessed the early findings and found no enhancement of CST regeneration (Lee et al., 2009). Similarly, no enhanced CST regeneration in mice that are deficient of Nogo-A receptor (NgR) that is supposed to mediate inhibition of all three myelin-associated proteins, Nogo, myelin-associated glycoprotein, and oligodendrocyte myelin glycoprotein (Zheng et al., 2005). Inhibition of NgR with their antagonist peptide NEP1–40 also yields controversy results of CST regeneration (Steward, Sharp, Yee, & Hofstadter, 2008). Nevertheless, a soluble function-blocking NgR termed NgR1(310)ecto-Fc, or AXER-204 is tested in rodent, monkey and is in clinical trial at present (Wang et al., 2020).

Promotion of CST regenerative sprouting by overcome of CSPG

Besides myelin-associated inhibitors, another major inhibitor is extracellular matrix molecules associated with glia scar around SCI site, such as chondroitin sulfate proteoglycans (CSPGs) (Tran, Warren, & Silver, 2018). Digestion of CSPG by chondroitinase ABC (ChABC) around C4 dorsal column injury site in rats promotes CST regeneration beyond the injury site, which is associated with functional recovery (Bradbury et al., 2002). Later, the same group delivers ChABC specifically into CST neurons by gene therapy using lentiviral vectors, which reduces CST axon die-back and promotes CST sprouting, but only in short range (Zhao et al., 2011). Following these exciting results in rodents, Rosenzweig et al. (2019) delivered ChABC below C7 lateral hemisection by multiple intraparenchymal injections in rhesus monkeys and found that ChABC delivery promotes significant amount of spared CST axonal sprouting from intact side into gray matter below the injury site where it controls hand function. Delivery of ChABC significantly improves hand function comparing with vehicle-injected controls using non-linear principal component analysis. This large animal primate study may pave a path for clinical translation of this strategy to promote CST regenerative sprouting after SCI.

Promotion of CST regenerative sprouting by genetic manipulation of certain genes

The extrinsic inhibitory environment after SCI is not the only factor to prevent CST axonal regeneration. The down-regulation of intrinsic regeneration-associated gene program in the adult neurons after SCI is another important factor for the failure of CST regeneration (Fagoe, Heest, & Verhaagen, 2014). A seminal study from Zhigang He's group shows that the tumor suppressor phosphatase and tensin homolog (PTEN) is one these genes that are responsible to down-regulate growth-associated genes, such as mammalian target of rapamycin (mTOR) (Liu et al., 2010). Genetic deletion of PTEN in mice reactivates mTOR expression and promotes substantial amount CST axon growth after SCI. Subsequently, the same group finds another cortical suppressor of cytokine signaling 3 (SOCS3) and deletion of SOCS3 can promote CST sprouting from uninjured CST axons to the denervated spinal cord in a unilateral pyramidotomy model (Jin et al., 2015). Co-deletion of SOCS3 and PTEN significantly enhances CST axon sprouting, which results in significant recovery of forelimb skilled locomotion. The deletion of PTEN and SOCS3, however, is at development stage, post-natal day 1, in these studies. A later study demonstrates that diminishing effect of PTEN deletion on CST regeneration in a low-thoracic dorsal hemisection model as the age of mice increases (Geoffroy, Hilton, Tetzlaff, & Zheng, 2016).

Besides deletion of PTEN and SOCS3, directly over-expression of developmentally regulated transcription factors, such as Krüppel-like factor (KLF) family and Sox11, in adult CST neurons by gene therapy improves their regenerative ability after incomplete C4–5 dorsal quadrant injury (Blackmore et al., 2012; Wang, Reynolds, Kirry, Nienhaus, & Blackmore, 2015). In addition, a recent study finds that a subunit of voltage-gated calcium channels alpha2delta2 involving synapse assembly negatively regulates CST axon growth and regeneration (Sun et al., 2019). Pharmacological suppression of alpha2delta2 with gabapentin promotes CST regenerative sprouting from the injury site into the intact side in a C5 lateral hemisection model in mice. The CST reorganization is associated with forelimb motor functional recovery (Sun et al., 2019). Notably, the up-regulation of alpha2delta2 parallels the maturation of CST in the development and the start of synaptogenesis. This indicates that synaptic activity may suppress axonal regeneration (Meve & Zheng, 2016). If this new mechanism for failure of axonal regeneration is proved to be true, it opens a new door to enhance axon regeneration by suppressing synaptic activity.

Robust CST regeneration into caudalized NPC graft after SCI

Transplantation of non-neural cells or fetal neural tissue

Although various above studies show sprouting and regenerative sprouting of CST axons after SCI, very few shows that transected CST can regenerate into a large clinically relevant injury site. A large injury site usually contains cavities where no axons can grow without a cellular substrate. Thus, various tissues or cell types are transplanted into SCI sites in combination with neurotrophin or other therapeutic interventions. However, transplantation of non-neural cells, such as fibroblasts, bone marrow stromal cells into the spinal cord lesion site, does not elicit any CST regeneration (Grill et al., 1997; Kadoya et al., 2016; Tuszynski et al., 2003). Transplantation of fetal (embryonic day 14) spinal cord tissues in a cervical over-hemisection site, however, does elicit very moderate regeneration of CST axons into lesion/transplant sites (Bregman et al., 2002). Sparse regenerated CST axons are usually restricted to the rostral a few hundred micrometers. Delivery of BDNF and NT-3 increases regeneration of CST axons, but the effect is very moderate (Bregman et al., 2002). This study indicates that early stage neural cells could serve as permissive cellular substrates for CST regeneration.

Transplantation of caudalized neural progenitor cells

Based on these previous studies, our group recently modified a transplantation protocol and demonstrated the robust regeneration of CST axons into the caudalized neural progenitor cell (NPC) graft (Kadoya et al., 2016) (Fig. 3). We transplanted freshly dissociated NPCs in single cell suspensions rather than embryonic spinal cord tissues, supported by growth factor cocktail embedding in fibrin matrixes. Transplanted NPCs survive, completely fill in the lesion site, and integrate very well with host tissue, resulting seamless and continuous connections from the transplant to the host tissue (Lu et al., 2012). The good integration of NPC transplant with host is critical since regeneration of CST requires direct contact of transected axon stumps with graft (Kadoya et al., 2016). In addition, CST regeneration requires caudalized and homotypic NPC grafts since CST fail to regenerate into telencephalic grafts, less into hindbrain grafts, and mostly into spinal cord grafts (Kadoya et al., 2016).

Injured CST axons not only robustly regenerate into the NPC graft, they also form synaptic connections with graft-derived neurons (Fig. 4) (Kadoya et al., 2016). Furthermore, our recent studies show that regenerated CST axons make appropriate connections with graft-derived spinal cord neurons (Dulin et al., 2018; Kumamaru, Lu, Rosenzweig,

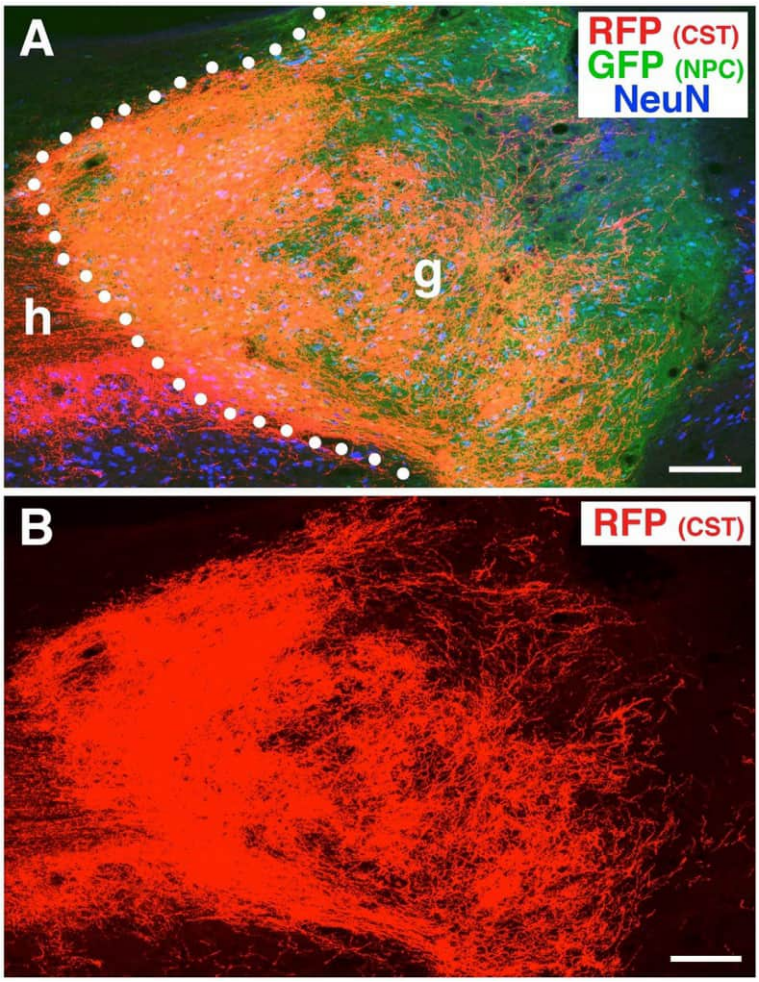

FIG. 3 Robust CST regeneration into NPC graft. (A and B) Triple immunolabeling demonstrates robust regeneration of RFP-labeled CST axons into GFP-labeled NPC graft with differentiation of NeuN-labeled neurons in a C3 dorsal column lesion site that completely transects the main CST. Dashed lines indicate host (h) and graft (g) in the rostral interface in a sagittal section view. Scale bar = 200 μm.

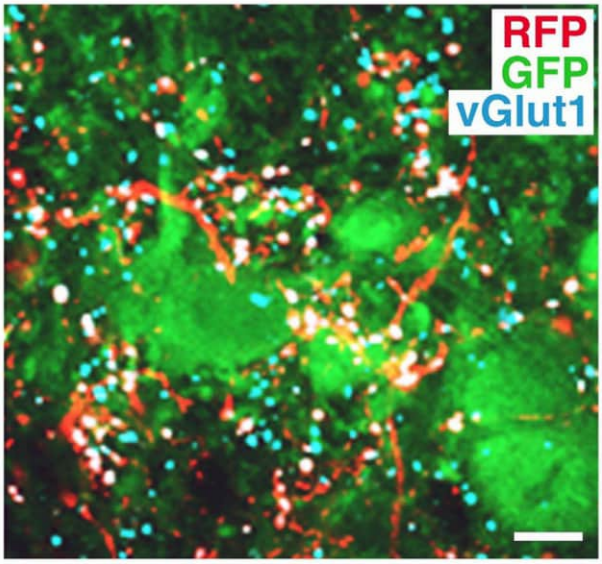

FIG. 4 Connectivity of regenerated CST axons with graft-derived neurons. Triple labeling for RFP, vGlut1, and GFP demonstrates that RFP labeled regenerated CST axons within GFP-labeled NPC graft exhibit bouton-like structures that co-localized with pre-synaptic marker vGlut1, indicating synaptic connections with grafted neurons. Scale bar = 4 μm.

Kadoya, & Tuszynski, 2019). *trans*-Synaptic tracing with herpes simplex virus reveals innervation of CST axons with pre-motor interneurons, such as V2a and Chx10+ excitatory interneurons and motor synergy encoder neurons positive for Satb1 and Ap2b immunolabeling (Levine et al., 2014), which are appropriate target of CST axons. On the other hand, CST axons avoid inappropriate targets of sensory cluster neurons derived from the spinal cord NPC graft. These results indicate that injured CST retains their intrinsic ability to recognize appropriate targets, which is important to achieve functional recovery after SCI.

For translational purpose, our group tests whether CST can regenerate into human NPC graft placed into a low-cervical hemisection site in non-human primate (Rosenzweig et al., 2018). As described above, the main CST in primate is located in the dorso-lateral funiculus that can be completely transected after lateral hemisection. CST axons regenerate by penetration into human fetal spinal cord-derived NPC grafts. Similarly, regenerated CST axons project toward Prdm8 positive pre-motor interneurons and avoid those Tlx3 positive sensory neuron clusters, indicating an appropriate connection with grafted human neurons (Kumamaru et al., 2019). However, it appears qualitatively that the density and distance of primate CST regeneration are less than rodent CST. This could be due to sub-optimal conditions of prolong cultured human neural progenitor cells in vitro.

Mechanisms of CST regeneration

In a follow-up mechanism study, our group discovers that transplanted NPCs are enable CST neurons to reverse to an embryonic transcriptional state for regeneration by transcriptome analysis (Poplawski et al., 2020). We find that the huntingtin gene (Htt) is a central hub in our analysis since conditional deletion of Htt in mice significantly reduces CST regeneration. The discovery of plasticity of injured adult CST neurons that can be reversed back to embryonic transcriptional state is significant since CST neurons and other injured adult neurons can be further manipulated to enhance their regeneration after SCI.

Reconnect injured spinal cord through neuronal relays

Although CST axons can regenerate into NPC graft, regenerated CST axons can only reach certain distance within the graft, usually about 2 mm (Kadoya et al., 2016). In a large severe and clinically relevant cervical contusive injury, regenerated CST can only reach the first half rostral NPC graft and leave the caudal half graft un-occupied. Unlike long-distance growth along the white matter in development, adult CST regeneration is similar to CST termination into gray matter neurons since NPC graft virtually re-constitutes spinal cord gray matter that contains large number of neurons (Lu et al., 2012), some of which are innervated by regenerated CST axons (Kadoya et al., 2016; Kumamaru et al., 2019). The limited distance of CST regeneration within the NPC graft is a challenge since CST signals rarely reach directly into spinal cord neurons caudal (below) to the injury to restore their motor functions.

On the other hand, graft-derived neurons can extend large number of axons into host, up to 29,000 axons counted at 0.5 mm caudal from graft in a rat upper-thoracic transection model (Lu et al., 2012). Graft-derived axons, just like developing neurons, travel along host white matter for long distance crossing several segments in both rostral and caudal directions (Lu et al., 2012). Indeed, our recent study demonstrates that host white matter myelin actually supports growth of NPC graft-derived axons (Poplawski et al., 2018). Grafted human NPCs extend their axons almost into the entire rat CNS axis (Fig. 5) (Lu et al., 2014, 2017). The large number and long-distance growth of graft-derived axons in the host are confirmed in a primate model of SCI where up to 150,000 graft-derived human axons are counted at 2 mm caudal to the lesion and reach up to 50 mm from the graft in caudal direction (Rosenzweig et al., 2018).

The ingrowth of regenerated CST axons and other supraspinal descending axons into the graft and the outgrowth of graft-derived axons into caudal host could constitute neuronal relays to re-connect injured CST neurons with their target spinal cord neurons below the injury (Fig. 6). Indeed, our electrophysiological study demonstrates partial recovery of evoked responses below a T3 complete transection site at T6 when stimulation is above the transection at C7 (Lu et al., 2012). This evoke response recovery depends on the presence of synapses in the graft since the application of kynurenic acid, the *N*-methyl-D-aspartic acid (NMDA) receptor blocker, abolishes this recovery. These results indicate excitatory synaptic transmission across the graft functions as neuronal relays. In addition, a recent study from our lab shows that stimulation of host CST by optogenetic method produces distinct and segregated neuronal network responses in the entire NPC graft in mouse SCI models. Furthermore, stimulation of graft-derived axons also elicits spinal cord neuronal responses below injury, indicating potential neuronal relay formation by grafted neurons (Ceto, Sekiguchi, Takashima, Nimmerjahn, & Tuszynski, 2020). These neuronal relays, in theory, could re-connect injured CSTs with spinal cord

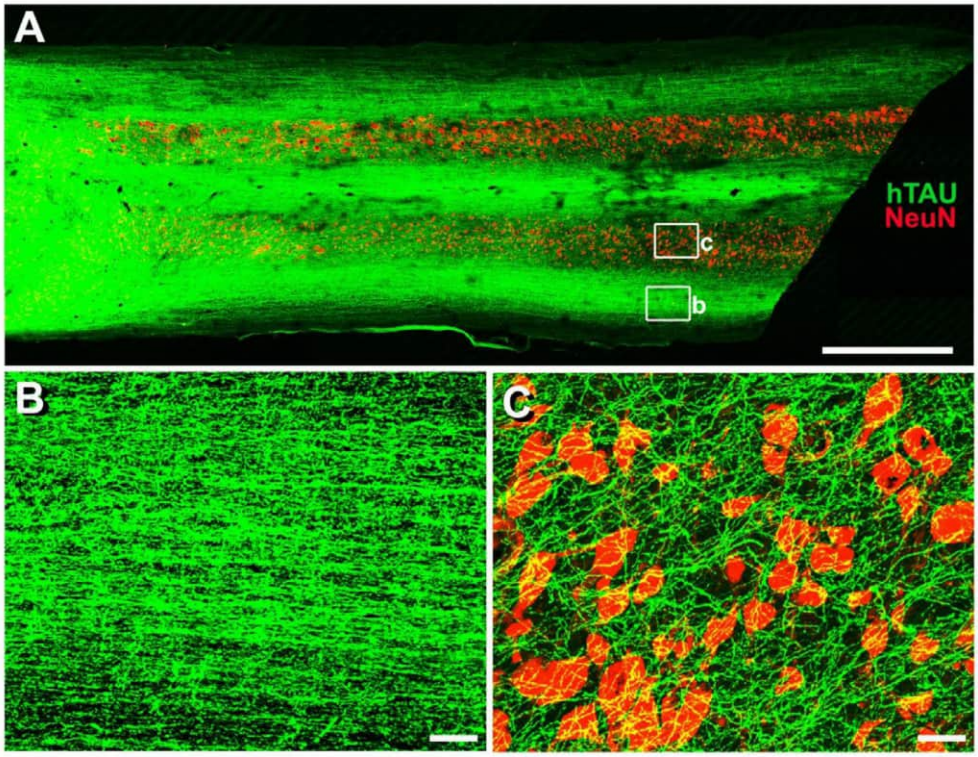

FIG. 5 NPC graft-derived axonal extension. (A) A low magnification horizontal image showing that human Tau labeled human neural progenitor cells (NPCs) extend their axons caudally into host rat spinal cord after NPC graft into the T10 bilateral contusion site for 3 months. NeuN labels both host and graft-derived neurons. Rostral, left, and caudal, right. (B and C) Higher magnification confocal *z*-stack images from the boxed area in panel (A) showing robust and extensive human graft-derived axonal growth in both host (B) white matter and (C) gray matter. Scale bar = 1 mm (A); 32 μm (B and C).

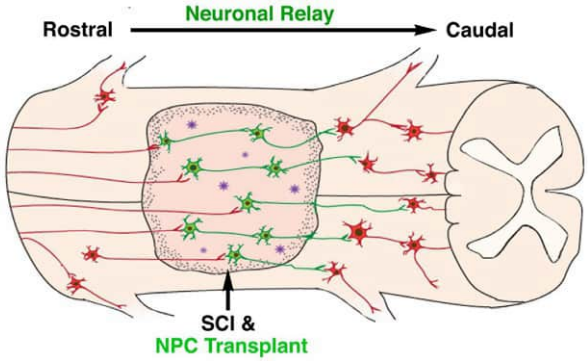

FIG. 6 A cartoon diagram of a neuronal relay formation by transplanted NPCs after SCI. Descending motor axons, including CST (*red*), regenerate into neural progenitor cell (NPC) transplant in spinal cord injury (SCI) site and make synaptic connections with graft-derived neurons (*green*). Graft-derived neurons extend their axons (*green*) into caudal host spinal cord and make synaptic connection with host spinal cord neurons (*red*). The reciprocal connection of host neurons with grafted neurons constitutes a neuronal relay formation. *Drawn by Audelia Arasheben.*

neurons below the injury by either mono-synaptic or poly-synaptic connections between grafted neurons that directly receive regenerated CST inputs and those grafted neurons that directly project into caudal spinal cord (Lu et al., 2019).

Future prospective

Since the major function of CST is cortical control of spinal cord activity, regeneration of CST is vitally important to restore motor function after SCI. Fortunately, studies demonstrate plasticity of CST system that is enable CST axon to sprout from uninjured axons, regenerative sprouting and regeneration either spontaneously or with therapeutic manipulations.

However, the major challenges remain, such as how to enhance CST sprouting in an incomplete SCI since there are always some spared axons where sprouting originates. For a large severe and complete SCI, promotion of CST regeneration crossing the injury site or through the neuronal relay is the only option. Although regenerated CST form functional synapses (Ceto et al., 2020; Jayaprakash et al., 2016; Kadoya et al., 2016), this does not spontaneously translate to motor behavioral recovery. The new circuit from regenerated CST and relay neurons need to be trained to be functional, especially for skilled and fine motor activity. In addition, whether regenerated CST axons are from the appropriate or inappropriate cortical area (forelimb vs hindlimb cortical area) in a defined cervical SCI is unknown. Promotion of CST regeneration from the appropriate cortical area is another potential challenge in the future.

Applications to other areas of neuroscience

Injury to the CST occurs not only in SCI, but also in stroke and brain injuries. The mechanism of spontaneous CST sprouting or therapeutic treatments to enhance CST sprouting and regeneration in SCI can be used for promotion of CST regeneration after stroke and brain injuries. However, the injury mechanism and the location of SCI are different from stroke and brain injuries. For example, a stroke results interruption of the blood supply to certain part of the brain, such as cortical area that contains CST neurons, and affects neuronal survival immediately. Restoration of blood supply at early stage of stroke along with therapeutic strategies discussed in this chapter could save CST neurons and restore their functional connectivity. Once a severe stroke occurs in the cortex and damages a large number of CST soma, a neuronal replacement strategy can be applied by transplantation of cortical NPCs. Our studies demonstrate early stage NPCs have great potential to extend their axons for long-distance growth (Lu et al., 2012). A recent study demonstrates that transplanted human embryonic stem cell-derived cerebral organoids into mouse cerebral cortices extend human axons along the corticospinal tract (Kitahara et al., 2020). These results indicate a great feasibility of a neuronal replacement therapy to restore CST connectivity for stroke and brain injuries.

Mini-dictionary of terms

Corticospinal tract: An axonal bundle that starts from cortical layer V pyramid neurons and travels through brain and brainstem to terminate in spinal cord for control of voluntary motor function of the body.

Spinal cord injury: A traumatic damage to the spinal cord that disrupts the connection between brain and the spinal cord below injury and results paralysis below injury.

Neural progenitor cells: Are cells that are capable of dividing a limited number of times and have the capacity to differentiate into a restricted repertoire of neuronal and glial cell types.

Central nervous system: Consists of the brain and spinal cord. It integrates the received information and coordinates and influences the activity of all parts of the bodies of bilaterally symmetric animals.

Motor synergy encoder: Represent a central node in neural pathways for voluntary and reflexive movement.

CSPG, chondroitin sulfate proteoglycans: Are proteoglycans consisting of a protein core and a chondroitin sulfate side chain.

PTEN, tumor suppressor phosphatase and tensin homolog: Is encoded by the PTEN gene and possesses lipid and protein phosphatase-dependent as well as phosphatase-independent activities.

Axon regeneration: A new growth occurs from tip of a transected axon, which may lead to reinnervation of its normal target.

Regenerative sprouting: Wherein new growth arises not from tip of transected axon, but from region of an axon close to injury sites.

Axonal sprouting: Injury disrupts a pathway that induces compensatory growth of new connections from nearby undamaged axons.

Key facts of corticospinal tract regeneration after spinal cord injury

Spinal cord injury irreversibly damages CST and leads to loss of voluntary motor function below injury.

Uninjured corticospinal tract can spontaneously sprout into denervated injury sites.

Injury can induce regenerative sprouting from injured corticospinal tract axons.

Therapeutic manipulation of inhibitory environment or enhancement of intrinsic growth capacity can promote CST sprouting and regenerative sprouting.

Transplanted neural progenitor cells can enhance robust regeneration of CST.

Summary points

- The corticospinal tract (CST) is the most important voluntary motor control system in humans.
- The regeneration of CST is vitally important for the restoration of the voluntary motor function after spinal cord injury.
- The CST has plasticity since they can spontaneously sprout from uninjured axons into denervated injury sites.
- The CST, however, cannot spontaneously regenerate after injury.
- Therapeutic manipulation is necessary in order to enhance CST regeneration or regenerative sprouting.

FES	functional electrical stimulation
FGF	fibroblast growth factors
GDNF	glial-derived neurotrophic factor
GH	growth hormone
GnRH	gonadotropin-releasing hormone
IGF-1	insulin-like growth factor-1
iPSCs	induced pluripotent stem cells
MSCs	mesenchymal stem cells
NGF	nerve growth factor
NPCs	neural progenitor cells
NT3	neurotrophin 3
NT4/5	neurotrophin 4/5
OECs	olfactory cells
OPCs	oligodendrocyte progenitor cells
SCI	spinal cord injury
TRH	thyrotropin-releasing hormone

Introduction

Spinal cord injury (SCI) causes temporary or permanent changes in the motor, sensory, and autonomic functions of the spinal cord.

The main symptoms of SCI vary according to where the spinal cord damage occurred. Cervical injuries produce partial or total tetraplegia, shown by paralysis of the four extremities, while injuries in the lower areas induce paraplegia, in which paralysis of the lower body occurs and, in both cases urogenital and digestive alterations.

SCI can directly induce the death of different cell types such as neurons, oligodendrocytes, and astrocytes. Once damage has been generated in the spinal cord, secondary alterations such as demyelination of axons and apoptosis processes in oligodendrocytes occur (see review, Fakhoury, 2015) (Fig. 1).

Thus, in this chapter, we will review the main trophic factors that are released spontaneously in patients when SCI occurs. Likewise, to those trophic factors that are secreted when patients undergo rehabilitation and finally, the perspectives of its use in clinical trials after SCI.

Currently, the concept of trophic factor is applied to substances of a known or unknown nature that have specific effects on cells or tissues through specific receptors called Trk and p75. Particularly when the trophic factor act, on neurons and glia, they are called neurotrophic factors and its actions include support the growth, survival, neurotransmitters release, and differentiation in different stages of development, in maturity or in regenerative processes.

Diagnosis and Treatment of Spinal Cord Injury. https://doi.org/10.1016/B978-0-12-822498-4.00037-3

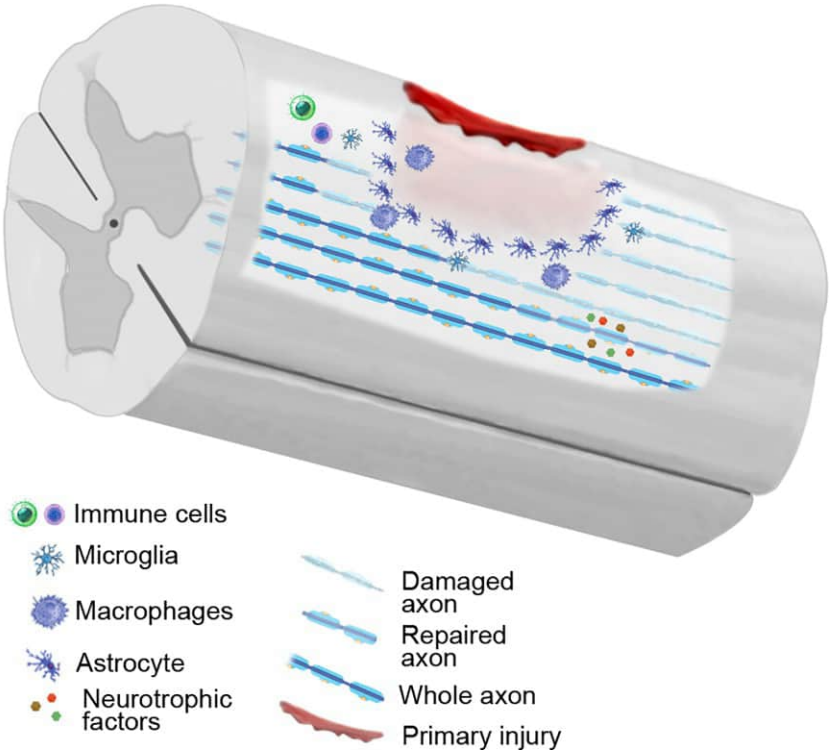

FIG. 1 Spinal cord injury. The image represents the main factors involved in the mechanisms of spinal cord injury. Initially, the primary lesion can produce a hemorrhagic site and edema, as well as cell death due to necrosis and apoptosis. On the other hand, the arrival of immune response cells to the site of injury occurs. At a later stage, a glial scar is formed that incorporates astrocytes and microglia. Therefore, many ascending and descending axons are disrupted and do not regenerate over long distances. Despite this, due to intrinsic neuronal plasticity and the presence of neurotrophic factors, it is possible that some axons grow to form new neuronal circuits.

Although there is evidence of spontaneous recovery, they will largely depend on the magnitude of the injury, spinal level, age of the injury, patient's condition, among others. However, spontaneous repair processes are initiated simultaneously in motor, sensory, and autonomous functions. Thus, the ability of intact corticospinal axons to sprout after SCI could present, as well as remyelination of injured axons.

Another approach to restoring the SCI and perhaps the most common strategy is rehabilitation and that produces environmental conditions that favor neurological recovery. Physical rehabilitation (exercise), electrical stimulation both directly to the muscle and to the spinal cord, produces motor and sensory improvements after SCI.

Cell therapies are used in order to create a suitable environment for restoration after SCI. The therapies include transplantation of stem cells, glial cells, and cells of the olfactory nervous system.

The treatment with trophic factor has been shown to improve conditions in different experimental animal models of SCI. The potential use of trophic factors in patients with SCI is evident, considering the possibility of improving the quality of life. However, a large number of clinical trials for its pharmacological use have to be carried out.

Role of neurotrophic factors in human neural plasticity after SCI

Spontaneous functional recovery in patients with spinal cord injury is limited, it occurs especially in patients in whom at least part of the sensory and motor functions has been preserved. This functional recovery stabilizes between 12 and 18 months and is mainly due to the conservation and sprouting of axons within the conserved medullary tissue adjacent to the injury site (Fawcett, Curt, Steeves, et al., 2006). After SCI, plasticity processes involving axonal regeneration can occur, this reconnection of axons involves the regrowth of transected axons through a site of injury toward their original synaptic targets, while other forms of axonal sprouting result in the reorganization of the circuit; all these processes can lead to restoration of function (Onifer, Smith, & Fouad, 2011). However, many of the axonal sprouts are usually not beneficial, and even cause adverse functional effects such as neuropathic pain, spasticity, and dysreflexia (Kathe, Hutson, McMahon, & Moon, 2016).

Neurotrophic factors can play an important role in structural and functional recovery after spinal cord injury and they are up or down regulation after the damage. These molecules are involved in axonal growth, remyelination, and modulation of the glial response after injury, among others (Afshari, Kappagantula, & Fawcett, 2009). This group of proteins is involved in the processes of natural plasticity after a spinal cord injury, which in patients has been described a relevant functional recovery without any type of treatment (Waters, Adkins, Sie, & Yakura, 1996). Not all neurons or spinal tracts express the same types of receptors, so they may preferentially be sensitive to a particular neurotrophic factor (Blesch, Fischer, & Tuszynski, 2012). The importance of the main trophic factors involved in the intrinsic recovery of neural tissue after the spinal injury is described below.

Nerve growth factor (NGF)

It is known that NGF activity increases after injury and that this factor is partly responsible for the initial regenerative response of the central nervous system, such as the stimulation of axonal sprouting and synaptic plasticity (Mocchetti & Wrathall, 1995). Besides, in the spinal cord, the NGF can influence neural responses to injury on cell types that display specific receptors to this factor, such as nociceptive sensory neurons and α motor neurons (Tuszynski et al., 1996; Verge, Richardson, Benoit, & Riopelle, 1989). The expression of NGF within the spinal cord induces a strong sprouting of nociceptive axons and hyperalgesia (Romero et al., 2000). Because the major trophic effects of NGF following SCI are seen in small-diameter sensory neurons, clinical trials have focused on investigating improvements in sensory components of neurological examinations and in pain assessments (McArthur, Yiannoutsos, Simpson, et al., 2000).

Brain-derived neurotrophic factor (BDNF)

BDNF has been shown to have neuroprotective and growth-promoting effects on different neuronal types after injury. It has particularly been observed in the rubrospinal, reticulospinal, and vestibulospinal tracts, as well as in the proprioceptive neurons of the nucleus of Clarke of the lumbar spinal cord. The neuroprotective effects can be attributed to the signaling cascades activated when BDNF binds to TrkB receptors. There is also evidence showing that BDNF can decrease glutamate-induced apoptosis-mediated cell death in the site of the injury (Almeida, Manadas, et al., 2005; Keefe, Sheikh, & Smith, 2017). However, in addition to the positive effects on the regeneration of motor tracts, the over-secretion of BDNF would only add to an environment that is favorable to not providing adequate plasticity and pain hypersensitivity after SCI (Coull, Beggs, Boudreau, et al., 2005).

Neurotrophin NT3 and NT4/5

These proteins are expressed in low amounts under normal conditions; however, after injury to the nervous system, inflammatory factors stimulate their expression and protect uninjured neurons by promoting the growth and repair of injured nervous tissue (Fang, Liu, et al., 2017). Also, the intrinsic secretion of NT-4/5 attracted Schwann cells to the injury site, causing myelination of affected axons at the injury site. Likewise, neurotrophins induced long-distance axonal growth of propriospinal and supraspinal axons (Engele, Schubert, & Bohn, 1991).

Glial-derived neurotrophic factor (GDNF)

Astrocytes, oligodendrocytes, and Schwann cells produce GDNF (Walker & Xu, 2018). After a spinal cord injury, a dense astrocytic glial scar occurs that surrounds the injury and this astrogliosis process is known to be positive, since it limits both the spread of excitotoxic molecules and the area of injury. In this sense, GDNF has been shown to positively modulate astrogliosis by improving the conditions of the lesion (Ansorena, De Berdt, Ucakar, et al., 2013). On the other hand, one of the mechanisms by which GDNF achieves functional improvement is by reducing secondary damage after SCI. GDNF has been shown to reduce the permeability of the blood–spinal cord barrier (BSCB) and down-regulate nitric oxide synthase (NOS). In this way, edema can be reduced and the survival of different neurons could be favored. In addition, neural apoptosis in the spinal cord after injury is also reduced and this also favors a decrease in secondary damage and greater recovery (Rosich, Hanna, Ibrahim, Hellenbrand, & Hanna, 2017).

Fibroblast growth factors (FGFs)

FGFs are present in the central and peripheral nervous system during development and throughout life, stimulating neuronal differentiation and migration. Its function in the context of spinal cord injuries focuses on the following aspects: stimulating the regeneration and regrowth of axons, guiding and accelerating the regeneration of the axon, carrying out the chemotactic

attraction of the cells of the immune response, as well as the stimulation of the formation of blood vessels; attenuate inflammation, astrocyte activation, and glial scar formation; finally, reducing the death of injured neurons and mediating the gene expression of injured neurons (Zhou, Wang, Li, Li, & Xiao, 2018).

Considering that spinal cord injuries in humans are generally incomplete, any therapeutic strategy that improves the cellular and synaptic function of surviving neurons is potentially useful. In this context, neurotrophic factors become in an important target for the clinical approach, which is discussed in the next sections.

Different environments enhance trophic factors delivery

Microenvironment consequences after primary injury in SCI involves hypoxia, ischemia, cellular swelling, free radical production, immune response, and several other factors that leads an injury tissue. Anti-regenerative profile promoted by damage, glial scar conformation, cellular death, and limited cellular infiltration conform chronic characteristics where axonal regeneration is unable and determinates clinical permanent disability in patients (Yang et al., 2020). Nerve disruptions avoid voluntary muscle contraction control and entails paralyzed muscles. Muscle atrophy determinate fiber lost, diameter decrease and metabolic conversions (Fu, Wang, Deng, & Li, 2016).

Currently, physical exercise is a fundamental therapeutic approach in the management of SCI, due, in part, to the fact that it increases the release of neurotrophic factors. This chapter describes its importance in the next section.

Exercise

Despite great efforts for new SCI treatments so far acute handling is based on high steroid doses and acute rehabilitation. Exercise enhances functional prognosis through neuroprotection actions beyond strength muscle improving.

Experimental studies demonstrate that exercise promotes blood–brain barrier strengthening, this integrity conserves an adequate filtration, and less edema occurs. During exercise, metabolic demand increase linked to further angiogenesis; regular physical practices enhance immune function, anti-inflammatory profile, and neuroprotection (Kohut et al., 2006). Neuroprotective actions also include enhancement of neurotrophins production, these polypeptides induce neuronal preservation, migration, and proliferation (Cobianchi, Arbat-Plana, Lopez-Alvarez, & Navarro, 2017).

Even when in acute injury neurotrophins concentration increase, trophic support decline over the time (Gold, Schulz, Hartmann, et al., 2003). Up-regulation of BDNF due exercise it considers the most important and assessed factor related to neural repair and brain circuit construction in humans. It is primarily produced in central nervous system (75% of circulating BDNF) but also platelets keep a large amount of BDNF protein. There is another neurotrophic factor extensively studied as NGF, NT3 in animal models related to exercise and neuroregeneration. Until now only BDNF has easy access for detection by enzyme-linked immunosorbent assay (ELISA) in humans (Gold et al., 2003; Leech & Hornby, 2017; Rosenfeld et al., 1995; Zeller, Abel, Rojas-Vega, Foitschik, & Strueder, 2015).

Different ways to exercise determinates neurotrophic factors release; variables like intensity, duration, and frequency impact on the expression of these factors, moderate to intermediate intensity are related to a better improve that observed in exhaustive exercise, daily no longer session induces an increase in plasmatic levels of BDNF. Several studies at different circumstances like adult healthy human male and female, SCI athletes, and multiple sclerosis patients, exhibit an elevates concentration of BNDF against control group when exercise develops (Gold et al., 2003; Leech & Hornby, 2017; Zeller et al., 2015).

BDNF is implied at multiple metabolic complex processes like neuroplasticity; up-regulation allows respond to situation as neural network reconstruction; added release is very susceptible to physical activity, and early time after injury exhibits a greater improve.

Furthermore, do not dismiss exercise is a primarily part of the SCI treatment conserving muscle and joins tone and flexibility, reduces contractures, and enhances internal organ functions (Rayegani et al., 2011). Likewise, functional magnetic resonance imaging (fMRI) and electroencephalogram (EEG) records show modifications in cortical sensorimotor area in SCI patients against healthy subjects when exercise perform, functional remodeling and provide functional recovery (Fu et al., 2016).

Injury level determinates the ability to perform physical rehabilitation, below the lesion no voluntary contraction exist. Electrical stimulation supplies neuronal connection, trough electric impulse promoting an action potential in a single muscle or group of muscles.

Electrical stimulation

Electrical stimulations (ES) appear as clinical application in 20th century, since the beginning stimulating electrodes were used to activate motor system and produce muscle contraction, although in some of the patient integrity of peripheral nervous system pathways it is intact, neuronal connection interruption between central nervous system and these tracts impair action potential generation, ES supply as an alternative to conserve muscle contraction, diminish atrophy and delay join alterations.

ES improves axon growth, myelin sheath formation and impact directly in reconstruction pattern independent of voluntary action. Transcutaneous and subcutaneous stimulation system can be applied directly in motor nerve or sensory nerve activation through spinal reflex activation (Yang et al., 2020).

The aim of stimulation determinates electrodes localization; muscle mass stimulation distributes depolarization to fibers around the application site, while nerve trunk stimulation depolarizes entire muscle. Orthodromic and antidromic activation generates a bidirectional stimulus and impacts to cortical brain reorganization (Milosevic et al., 2020).

Currently, complex patterns of stimulations make possible limbs movements control and gait reproduction consequently of transcutaneous implants electrode stimulation, this technique is referred like Functional Electrical Stimulation (FES). Rehabilitation was the first objective of FES, considering some experiments that exhibit TrkB receptor expression and BDNF serum levels enhance after electrical stimulation and brains network reorganization. FES became a treatment strategy (FEST) while patients could stand up and develop gait movements supporting by team assistances moving around short distances (Hogan, Hamilton, & Horner, 2020).

Recently brain–computer interface (BCI) an emerging technology, potency bidirectional stimulation utilizing FES movements control and brain outputs signals that synchronize FES and cortical instructions. Simultaneous activations enhance networks reconstruction (neuroplasticity). Few SCI patients have participant on this technology.

Electrical stimulation similar to physical activities, increase neurotrophic factor release, brain and spinal circuit reorganization, neuroplasticity and improve motor function (Rojas Vega et al., 2008).

Reinforce of neuronal reorganization could be supported by cellular implanted, another way to increase neuroplasticity and neurotrophic factor release.

Cell transplantation

Replace of injury neuronal cells is one of the objectives of cell transplantation; additionally, they promote axon regeneration, neurotrophic factor release and myelination (Griffin & Bradke, 2020).

Clinical application of these cells started since 2010, a relative new strategy, Geron Corporation explored the introduction of oligodendrocyte progenitor cells (OPCs) at injured place, ethical component was very discussed field about origin of the cells, preservation place and growth methods, all these components were determined with a strict limitation (Jin, Medress, Azad, Doulames, & Veeravagu, 2019).

Clinical assays implement different cells for SCI transplantation including neural progenitor cells (NPCs), Schwann cells, olfactory cells (OECs), mesenchymal stem cells (MSCs) and induced pluripotent stem cells (iPSCs) (Jin et al., 2019). Fig. 2 shows the trophic factors released in the different therapeutic approaches.

Additionally, route of administration is a critical point, and determinates potency of treatment most of them are invasive: intramedullary, intrathecal, intravenous, and percutaneous. All administrations represent a certainty risk but also allows introduce cells by infusion or graft containing cells.

Furthermore, after cell transplantation, the rate of cell differentiation and survival is low. This makes it necessary to administer more cells in a second application.

Currently, clinical trial in phase 1 or 2 are a few (<30); they are evaluating safety adverse effects and viability of management (Silvestro, Bramanti, Trubiani, & Mazzon, 2020).

Mesenchymal stem cells obtain from: bone marrow, umbilical cord blood, adipose tissue, is one of the experimental transplanted cells, promotes conditions against apoptosis and substitutes neuronal cell death. Side effects after administration consist in fever, headache, abdominal distention, and backache (Dasari, Veeravalli, & Dinh, 2014). These patients are evaluated through MRI for long periods (more than a year) regarding adverse effects as tumor (ectopic tissue), death or immune reactions. A main risk of stem cell transplantation involves tumors and phenotype conversion in transplanted cells.

Regarding of these treatment options, different techniques exist to over expression and release of neurotrophic factors, exercise and electrical stimulations are safety than cell transplantation although all of them represent an alternative option to improve motor activation in SCI patients.

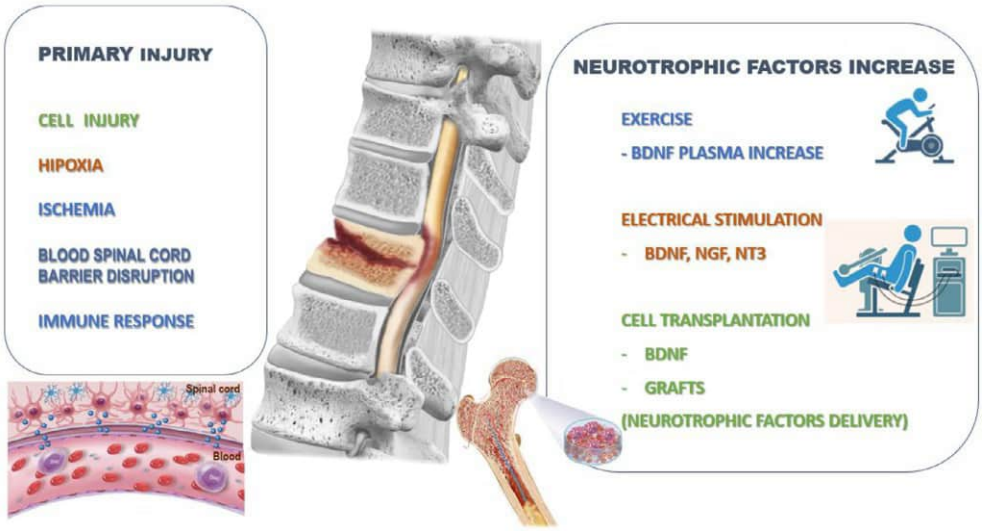

FIG. 2 Representative image of mechanisms presents during primary injury against possible interventions that enhance neurotrophic factor release as a possible management for SCI patient.

Therapeutic potential of trophic factors

Trophic factors mainly participate in the regulation of neuron survival or repair, in the generation of synaptic plasticity, in the secretion of neurotransmitters and in the induction of neuritic changes such as axonal growth, as well as in glial recovery (Harvey et al., 2015; Keefe et al., 2017) (Fig. 3).

Most of them have been tested in animal models with SCI, where their neurotrophic capacity is shown, improving motor conditions, sensitivity, and autonomic functions.

The main neurotrophic factors and their effects and, where appropriate, clinical trials in patients with spinal cord injury are described below.

The first trophic factor to be characterized was the NGF, which regulates nerve regeneration by promoting growth, the formation of new synaptic contacts, inducing differentiation in certain neuronal types, and the recovery of constitutive structures of neural networks. These facts have been described in experimental animals (Xu, Wu, Qin, et al., 2019). However, there is no clinical trial in patients that supports its administration.

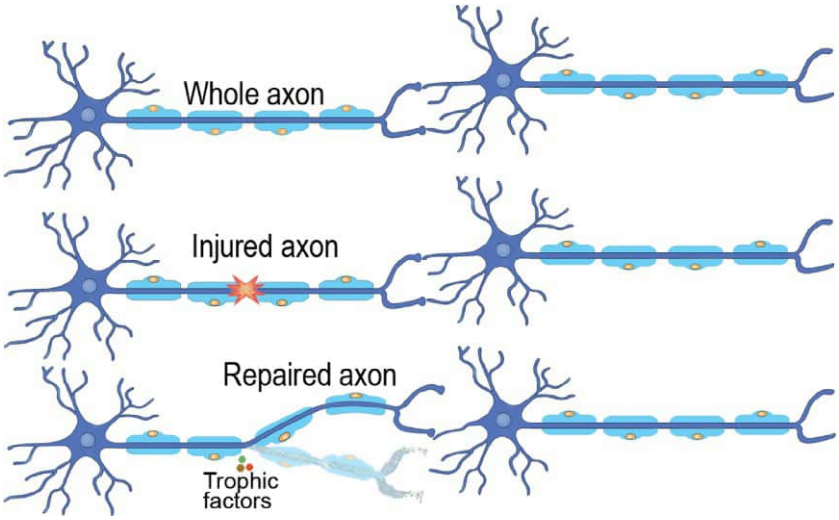

FIG. 3 Schematic representation of trophic factor-induced neuronal plasticity after spinal cord injury. Integral neurons with synaptic contact with the whole axons. After injury, the axon remains incomplete but still viable. Finally, a possible mechanism is shown by which an axon can regenerate induced by trophic factors and return to make synaptic contact with the next neuron.

The BDNF participates in neuroprotective functions in both neurons and glial cells. It induces neuronal growth, particularly of axons and their regeneration in the event of neurological lesions, as well as axonal remyelination (Keefe et al., 2017). One of the most important risks in the management of these neurotrophic factors is their side effects. For this reason, treatment with these factors requires more studies that allow it to be used in patients with SCI.

In the case of neurotrophins, NT-3, NT-4, and NT-5, their role within the nervous system is to repair damaged neurons and promote growth, as well as induce neuronal differentiation (Veneruso et al., 2019). Currently, there is no treatment protocol for patients with SCI, only experimental trials in animal models.

The GDNF promotes axonal recovery and regulates the proliferation of glial cells such as astrocytes. In addition, it has anti-inflammatory effects, which favors the reduction in the size of the lesion, thereby improving the environmental conditions for its recovery (Rosich et al., 2017; Walker & Xu, 2018). Treatment with this neurotrophic factor has been tested in experimental animals, but there are no reports that propose a treatment scheme for patients with SCI.

The ciliary neurotrophic factor (CNTF) plays an important role in the survival of injured nervous tissue, either directly in neurons in regenerating axons or in damaged oligodendrocytes (Ong, Pinese, & Chew, 2019). It is perhaps the trophic factor that could have the greatest impact on a possible treatment for neuronal regeneration in the case of patients with SCI. Its properties are very specific and with few side effects.

Other neurotrophic factor is FGF which induce axonal regeneration and recovery of damaged neurons. Likewise, they induce the activation of astrocytes and the reduction of inflammation (Zhou et al., 2018). A clinical study in patients with SCI, FGF administration after 24 months of treatment, partially improved sensory and motor functions. The most important inconvenient is that an invasive method is required for application of FGF since it is administered at the site of injury (Wu, Huang, Chen, et al., 2011).

Insulin-like growth factor 1 (IGF-1) is involved in axon growth, oligodendrocyte survival, and myelin recovery. In addition, it has antioxidant effects (Allahdadi, de Santana, Santos, et al., 2019). Unfortunately, there are no reports of studies performed in clinical trials with SCI patients treated with IGF-1, only in experimental models in animals with lesion of spinal cord.

Molecules with properties of trophic factor in clinical trials

It has been described that Gonadotropin-releasing hormone (GnRH) presents neurotrophic effects in experimental animal models with traumatic SCI. Recently has been demonstrated the presence of GnRH receptor in the spinal cord of humans (Díaz-Galindo, Calderón-Vallejo, Hernández-Jasso, et al., 2020). The use of synthetic analogues of GnRH such as leuprolide acetate, also improve the conditions of SCI. Leuprolide acetate administered via intramuscular injection, cross the blood-spinal cord barrier (Barrera, Kastin, Fasold, & Banks, 1991). We have reported that in patients with chronic SCI, intra-muscular administration of leuprolide acetate each month during 6 months induces recovery in ASIA (American Spinal Injury Association) scale scores of motors, sensory and functional independence measure (Quintanar, Díaz-Galindo, Calderón-Vallejo, et al., 2018). The main advantage of this treatment is of easy and safe application and that it is a non-invasive method (Fig. 4).

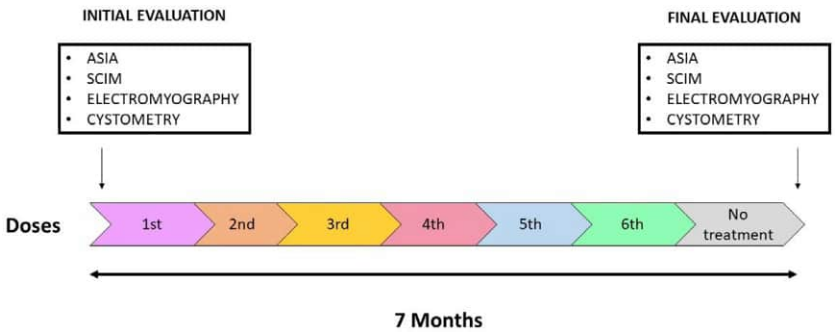

FIG. 4 Scheme of a possible treatment with a GnRH agonist (leuprolide acetate) as a trophic factor administered intramuscularly every month for 6 months in patients with SCI (Quintanar et al., 2018). ASIA score, American Spinal Cord Injury Association; SCIM, Spinal Cord Independence Measure.

Thyrotropin-releasing hormone (TRH) stimulates the release of the thyroid stimulating hormone produced by pituitary gland, which stimulates the thyroid gland for the secretion of thyroid hormones (Fröhlich & Wahl, 2019). Studies have described that patients with SCI treated with TRH, improves of motor or sensitive functions when they were treated within 12 h after trauma. They were evaluated up to 4 months after lesion (Pitts, Ross, Chase, & Faden, 1995). It is possible that the neuroprotective effect of TRH and its analogues is through the stabilization of neuronal membrane, its anti-inflammatory properties and its antioxidant capacity (Faden, Vink, & McIntosh, 1989).

Growth hormone (GH) is a peptide produced by pituitary gland. Has been described its role in neuroregeneration processes, promotion of innervation and neurogenesis (Arámburo, Alba-Betancourt, Luna, & Harvey, 2014; Martínez-Moreno, Calderón-Vallejo, Harvey, Arámburo, & Quintanar, 2018). A clinical case has been published in a patient with incomplete spinal cord development and impaired limb motor activity in which was administered with GH. Treatment induced an improvement in motor function (Devesa, Alonso, López, et al., 2017). This neurotrophic effect could be due to the fact that GH participates in the expression of neurotrophins such as BDNF and IGF-1 (Sharma, 2007).

The hormone melatonin is a peptide produced by the pineal gland (Aygün, Kaplan, Odaci, Onger, & Altunkaynak, 2012). In SCI rats, systemic melatonin administration during 4 weeks induces a reduction of free radical, and therefore oxidative stress, giving its recovery (Erşahin, Özdemir, Özsavcı, et al., 2012).

The estrogens are hormones produced mainly in the ovaries and they have neuroprotective effects. In SCI animal models, treatment of estrogen 48 h after the lesion induces a reduction of calpain and caspase-3 expression which have anti-apoptotic effects (Samantaray, Sribnick, Das, et al., 2010). Likewise, in SCI rats, locomotion was improved and neurons of the spinal cord, the survival was higher after estrogen treatment (Table 1) (Kachadroka, Hall, Niedzielko, Chongthammakun, & Floyd, 2010).

The most important challenges that have to be considered in clinical use of trophic factors in patients are: (a) its half-life is very short, (b) in most cases they do not cross the blood-spinal barrier, (c) the administration would be topical, so they would use invasive techniques (surgical), (d) possible non-specific effects on uninjured tissue, (e) adverse side effects, and (f) the economic costs of a possible treatment.

However, perhaps one of the most important and pending challenges is that there are preclinical trials that have been performed in experimental models using trophic factors and that have not yet been tested in patients with SCI.

It is possible that with the conjunction of several simultaneous therapeutic approaches, such as rehabilitation and the administration of trophic factors, it may give a better result in terms of neurological recovery, thus giving a better quality of life for patients with SCI.

Applications to other areas of neuroscience

Because of the complex nature of the nervous system, when injuries occur to it, possible treatment approaches are also complex. To understand the pathophysiological phenomena that occur with SCI, experimental animal models are initially used. Later the translational consideration would be its applicability in patients with SCI. In the specific case of the application of neurotrophic factors such as nerve growth factor, brain-derived neurotrophic factor, neurotrophin 3 and 4/5, glial-derived neurotrophic factor, fibroblast growth factors, ciliary neurotrophic factor, and insulin-like growth factor-1, have been widely studied. However, not all these factors have been clinical trials, either due to the routes of administration, their chemical characteristics or the adverse effects that they may produce. On the other hand, there are molecules with trophic properties such as gonadotropin-releasing hormone, thyrotropin-releasing hormone, growth hormone, melatonin, and estrogens. These molecules have among their functional properties, neuronal plasticity. Due to these properties, these hormones have been used for the treatment of spinal cord injuries both in experimental models and in some clinical trials. The results observed include improvements in motor, sensory, and autonomic function.

It is possible that these trophic factors can also be used in neurological lesions in other sites of the nervous system such as peripheral nerves and in the brain.

TABLE 1 Summary of trophic factors and their possible therapeutic effects in spinal cord injury patients.

TROPHIC FACTOR	POTENTIAL TERAPHEUTIC EFFECTS IN SCI	REFERENCES
BDNF	✓Stimulate neuroplasticity and neural network reconstruction as well as modifications in cortical sensorimotor area. ✓Conserving muscle and joins tone and flexibility, reduces contractures, and enhance internal organ functions. ✓Develop gait movements supporting by team assistances moving around short distances.	Rayegani et al., 2011; Fu et al., 2016; Hogan et al., 2020.
NT-3, NT-4 and NT-5	✓Repair damaged neurons and promote growth. ✓Attracted Schwann cells to the injury site, causing myelination of affected axons at the injury site. ✓Induced long-distance axonal growth of propriospinal and supraspinal axons.	*Engele et al., 1991; Veneruso et al., 2019.*
GDNF	✓ Promotes axonal recovery. ✓ Regulates the proliferation of glial cells such as astrocytes. ✓It has anti-inflammatory effects, which favors the reduction in the size of the lesion.	Rosich et al., 2017; Walker et al., 2018.
CNTF	✓ Plays an important role in the survival of injured nervous tissue, either directly in neurons in regenerating axons or in damaged oligodendrocytes. ✓ In SCI patients, its properties are very specific and with few side effects.	Ong et al., 2019.
FGF	✓ Induce axonal regeneration and recovery of damaged neurons. ✓ induce the activation of astrocytes and the reduction of inflammation. ✓ In SCI patients, partially improved sensory and motor functions.	Zhou et al., 2018; Wu et al. 2011.
IGF-1	✓ Involved in axon growth, oligodendrocyte survival, and myelin recovery. ✓ It has antioxidant effects.	Allahdadi et al., 2019.
GnRH and analogues	✓ In SCI patients, a partial recovery of motor and sensorial functions. ✓ Increase in functional independence measure in SCI patients.	Quintanar et al, 2018.
TRH and analogues	✓ In SCI patients, a partial recovery of motor and sensory functions. ✓ Anti-inflammatory properties and antioxidant capacity.	Fade et al, 1989.
GH and analogues	✓ In SCI patients, an improvement in motor function. ✓ Stimulate the release of BDNF and IGF-1.	Devesa et al. 2017; Sharma, 2007.
Melatonin	✓ Reduction of oxidative stress, thereby reducing the deterioration of the spinal cord lesion.	Ersahin et al. 2012.
Oestrogens	✓ Reduction of apoptosis. ✓ Improve in locomotion. ✓ The survival of spinal neurons was higher.	Samantaray et al., 2010; Kachadroka et al., 2010.

The column on the left side indicates the name of the different trophic factors. The potential therapeutic effects of each factor are listed in the middle column. The right column contains the information of the references that can be consulted for more details.

Mini-dictionary of terms

Spinal cord injury: An alteration of the spinal cord, caused by trauma or disease. A spinal cord injury often causes permanent loss of strength, sensation, and mobility below the site of injury.

Trophic factors: A group of substances, most of them of a protein nature that, together with hormones and neurotransmitters, induce morphofunctional changes in tissues.

Neural plasticity: Is the ability of the nervous system to change its structure and function as a reaction to the diversity of the environment.

Electrical stimulation: It is the technique that uses electrical current to cause a muscle contraction. Using a device called an electrostimulator, an electrical current is generated to induce muscle contractions or tingling sensations that serve to prevent injuries, train or treat muscles, obtain a therapeutic effect and improve performance.

Physical rehabilitation: A group of methodologies that aims to recover and improve the functional capacity and quality of life of those people who suffer from disability due to illness or injury.

Neurotrophins: A family of proteins which regulate the generation, survival, proliferation, differentiation, and death of neurons in the peripheral and central nervous system. They include NGF, BDNF, NT3, and NT4/5.

Glial-derived neurotrophic factor: A polypeptide factor that binds and activates the TrkB receptor, it has an important role in the physiological processes underlying the plasticity and development of the nervous system.

Ciliary neurotrophic factor: A member of the interleukin-6 family of cytokines. This factor is a differentiating cytokine that drives cells toward a predominantly astrocytic fate.

Fibroblast growth factors: A family of 18-member proteins grouped in 6 subfamilies that have biological activity during early embryo development regulating positive and negative cellular growth, differentiation and survival and during adulthood, mediating metabolic functions, tissue repair and regeneration.

Insulin-like growth factor-1: A polypeptide hormone secreted in multiple tissues by the effect of growth hormone. Most of circulating IGF-I is of hepatic origin and it has been seen to be important in modulating of neurogenesis.

Key facts of spinal cord injury

In the world, more than a million people have affectations caused by SCI. Currently there are no treatment proposals that can give a full recovery of SCI. Depending on the degree, age, level of the injury, and treatment, the degree of neurological recovery and therefore functional improvement of the patient with SCI can be predicted.

Different therapeutic strategies have been developed to improve the conditions of patients with SCI.

Key facts therapeutic approaches

Among the strategies is rehabilitation, which include physical exercise, electrical stimulation, and cell transplantation. These strategies have in common that among their nerve regeneration mechanisms is the induction of trophic factors.

The trophic factor acts on neurons and glia, they are called neurotrophic factors and its actions include support the growth, survival, neurotransmitters release and differentiation in several stages of development, in maturity or in regenerative processes.

Another possible strategy for recovery from spinal cord injury is the administration of neurotrophic factors or molecules that have neurotrophic properties.

Either in preclinical protocols or in clinical trials, different trophic factors have been tested, including nerve growth factor, brain-derived neurotrophic factor, neurotrophin 3 and 4/5, glial-derived neurotrophic factor, fibroblast growth factors, ciliary neurotrophic factor, insulin-like growth factor-1, gonadotropin-releasing hormone, thyrotropin-releasing hormone, growth hormone, melatonin, and estrogens.

The results obtained after carrying out any of the strategies, be it rehabilitation or the administration of trophic factors, have been improvements in motor activity, sensory, and autonomic function with the perspective of giving a possible better quality of life for patients with SCI.

Summary points

- Spinal cord injury in patients causes motor, sensory and autonomic dysfunction.
- There are therapeutic approaches to induce neurological recovery in different experimental models or in clinical trials.
- Rehabilitation induces neurological recovery through the release of neurotrophic factors.

- Therapeutic treatment with directly administered trophic factors induces neurological recovery in SCI.
- There are preclinical trials that have been performed in experimental models using neurotrophic factors and that have not yet been tested in patients with SCI.

Introduction

Damage to the spinal cord can be a life-changing event, usually occurring suddenly as a result of an accident, and presenting both acute and long-term medical effects to individuals and their families. Because these events usually happen unexpectedly, suddenly the individual is thrown into the chaos of the health care system. Rarely do people have any idea of the implications on future health, lifestyle, or economic consequences of this kind of event. The impact on the affected individual is profound, producing both paralysis and medical complications to many body systems. Medical prognostication is often uncertain, and many myths surround spinal cord injury (SCI; sciprogress.com, 2020).

Epidemiology of spinal cord injury

Over the past 50 years, the age at time of acute spinal injury has increased by a decade or more, but still, the event affects individuals in the prime of their lives, currently averaging 43 years of age (National Spinal Cord Injury Statistical Center, 2020a). Nearly 80% of all SCI individuals are male. As a result of the age at onset, consequent effects have major socioeconomic impacts on work-lives, family income, and life roles. Despite many improvements in motor vehicles, motor vehicle accidents represent approximately 40% of all SCI cases, with falls accounting for another 30%, gunshots 13.5%, and sports-related causes about 8% (National Spinal Cord Injury Statistical Center, 2020a). Medical issues such as transverse myelitis and intraspinal hemorrhages account for the remainder. Regardless of cause, the effect is hugely traumatizing.

There are approximately 17,700 new cases of SCI each year, representing an annual incidence of 54 cases per 1 million population. Because the pathology is often lasting, it is estimated that around 300,000 persons with SCI are currently living in the United States (National Spinal Cord Injury Statistical Center, 2020b). SCI related disability may affect the cervical, thoracic, lumber and sacral portions of the spinal cord structures, with higher level injuries producing more disability (National Spinal Cord Injury Statistical Center, 2020b). The physical impacts on the spinal cord may produce an incomplete injury with some functions retained or may result in a near-complete loss of function distally. Nearly 60% of all SCIs are at the cervical level producing tetraplegia, and 2/3rds of those are incomplete. Of the 40% remaining injuries producing paraplegia, half are incomplete (National Spinal Cord Injury Statistical Center, 2020b). Less than 1% of affected individuals experience complete recovery by the time of hospital discharge (National Spinal Cord Injury Statistical Center, 2020b).

Life impact and medical support

Everyday activities, from prior independence of basic life activities through vocational function undergo massive change. SCI greatly affects a person's level of independence in mobility, self-care and economic well-being. A little over 30% of affected individuals are married at the time of injury, with 60% single or divorced at injury (National Spinal Cord Injury Statistical Center, 2020b). While nearly 60% are employed at the time of injury, by the end of year one post-injury only about 12% are (National Spinal Cord Injury Statistical Center, 2020b). As a consequence, reliance upon social support systems greatly increases. The level of such support systems varies greatly across the United States, rarely covering all the injured person's needs, especially immediately following injury.

Diagnosis and Treatment of Spinal Cord Injury. https://doi.org/10.1016/B978-0-12-822498-4.00038-5

Medical care for acute spinal cord injury has changed significantly over the years, with improvements in surgical and medical management resulting in improved survival. But as the physiologic impacts of SCI are usually long-term, this presents a need for comprehensive rehabilitation in order to strengthen the areas affected and instruct the injured person in self-management skills including dressing, hygiene, toileting and skin care, in addition to teaching mobility skills such as wheelchair use and other supported mobility needs. During the 1970s, most SCI-affected individuals spent months (average 142 days) in inpatient rehabilitation facilities learning these skills, gaining competence in self-management, and educating families and immediate caregivers on appropriate ways of providing needed support. By discharge, these skills had been practiced, needs anticipated and support structures provided. During those years, the average length of stay in an inpatient rehabilitation facility for a cervical cord injury was around 5 months and during this period the individual often had opportunities for weekend passes to practice skills in their home environment. Persons with paraplegia stayed for 2 months or longer, with similar opportunities to practice home skills. During those years, the rehabilitation inpatient staff team frequently included physical therapists, occupational therapists, social workers, recreation therapists, vocational counselors and psychologists to teach, guide and support individuals with SCI in the areas affected by their injury. Health care systems have changed dramatically since then, with the overall average length of stay currently just over 1 month (National Spinal Cord Injury Statistical Center, 2020b). Rehabilitation staffs have shrunk as well, with only basic therapy needs provided in many American inpatient rehabilitation facilities. Specialty SCI rehabilitation hospitals may have much larger staffs and longer lengths of stay, but funding for such care is not available for many acute SCI patients. As a consequence of these systematic changes in care provision, there are larger burdens placed upon caregivers and patients.

The dramatic compression of lengths of stay result in a much busier hospital day, especially given that nearly 40% of traumatic SCI patients have other injuries in addition to their spinal cord and 80% will have undergone spinal surgeries (National Spinal Cord Injury Statistical Center, 2020b). There are common co-morbidities including traumatic brain injury and thoracic and abdominal trauma. Focus is on physical recovery, wound healing, pain management and other medical needs, as well as rehabilitation therapies and education. Individuals with significant pain issues have consequent learning difficulties that interfere with the teaching process. The burden of healing, coping, adaptation, and multi-tasking overwhelms even emotionally stable individuals. The cliché of drinking from a firehose is not an exaggeration. The inpatient stay period is intensely stressful for all, patients, spouses, family, and caregivers.

Spinal cord injury after-effects

There are common medical changes resultant from the injury. Bladder management poses issues for about 75% of individuals with SCI, with a variety of urologic adaptations needed, including intermittent catheterization, indwelling catheters, or some form of urinary diversion (National Spinal Cord Injury Statistical Center, 2020b). Medical complications of these alternative solutions may include subsequent urinary tract infections (National Spinal Cord Injury Statistical Center, 2020b). Bowel management may also pose issues, requiring modifications of typical routines, medications and physical techniques which may necessitate caregiver aid. Education regarding skin care is an essential part of the inpatient training process, but follow-through is critical post-discharge and this too may pose caregiver burden, especially if pressure sores occur (National Spinal Cord Injury Statistical Center, 2020b). The need for family and caregiver education is critical to support the person with an acute SCI both medically and with mobility needs.

The preponderance of SCI survivors (87.4%) are discharged to a private home (National Spinal Cord Injury Statistical Center, 2020b). Architectural accessibility of the home to mobility limitations more often than not presents significant problems, especially for those with higher level injuries. Thus, architectural barriers are routinely problematic, as 60% of individuals with SCI rely on a wheelchair for mobility, including both manual and powered chairs (National Spinal Cord Injury Statistical Center, 2020b). In many homes, bedrooms are upstairs, bathrooms are small and inaccessible to wheelchairs and entry and exit present their own challenges. Steps and stairs, narrow doorways, cupboards, and toilet areas cause difficulties for most at discharge. Only rarely is funding for architectural modification available. Transportation poses a common problem, as many vehicles are difficult to enter and exit for someone in a wheelchair and public transportation is often unavailable, especially for rural residents.

The changes in spinal cord injury care over the past decades are many, with some good news in reduction of medical complications, more sophisticated spinal surgery resulting in enhanced neuro recovery and better understanding of medical needs. But there is also less positive news in terms of the reduction in lengths of stay resulting in less opportunity for patient and family education, less medical oversight in the months immediately following the injury and less emphasis on community re-entry education. Community support systems are insufficient. As a consequence of these latter issues, the Multi-family Group Education (MFG) process poses a real opportunity in the long-term approach to the many problems posed by SCI.

Impacts of SCI on family caregivers

There is nearly always a need for caregiver support of people with SCI. For married individuals, this usually falls to the spouse, placing both physical and substantial emotional demands. For unmarried persons, often this role falls to the family and obviously such support varies greatly in time, interest and ability. The caregiving position encompasses more than physical assistance and often includes educating, advising, financially supporting, advocating for and becoming the prevention / management specialist for the injured family member (Guilcher et al., 2012). Family caregivers are thrust into learning much of this on the fly and often don't know how to accomplish all the necessary tasks. As a result, they often become as, or more stressed and overwhelmed as the person with SCI by the added responsibility and adjustments needed to their daily lives. They can experience frustration, isolation and feelings of guilt, as well as resentment toward the injured family member they care for (Kester, Rothblum, Lobato, & Milhous, 1988). Qualitative research on the experience of family caregivers for people with SCI indicates that caregivers experience deterioration in their relationship with the person who has SCI and that they require intentional re-building and maintaining of their relationships (Jeyathevan, Cameron, Craven, Munce, & Jaglal, 2019). Spouses who become caretakers of an SCI injured partner have been found to have significantly more depressive affect than their spouse with SCI and have significantly more physical and emotional stress, burnout, fatigue, anger and resentment, depressive affect and somatic depression than spouses who are not caregivers (Weitzenkamp, Gerhart, Charlifue, Whiteneck, & Savic, 1997). Negative psychological and physical health impacts on caregivers have been indicated across countries and cultures (Ebrahimzadeh et al., 2013).

In an examination of the unique contribution of social support to SCI caregiver burden researchers have found that social support, social interactions, and social integration are significant predictors of caregiver burden, suggesting that interventions such as MFG that promote social support, interaction, and integration hold the potential to decrease caregiver burden (Rodakowski, Skidmore, Rogers, & Schulz, 2012). There is a pressing need for individualized education, support and coaching not only for individuals with SCI, but also for their caregivers, particularly when those caregivers are family members (North, 1999). This need begins immediately and should be in place upon discharge from the hospital.

Impact of multiple family groups (MFG) on psychiatric outcomes

Chronic health conditions require multiple adjustments for both those afflicted and their family caregivers. They are invariably extremely isolating conditions that require coping skills both by patients and their family caregivers. There is now accumulated evidence over a number of decades which supports the idea that, for a number of chronic conditions, a combination of education, support and problem-solving services improves rehabilitative outcomes, community supports and in some cases reduces caregiver burden (Glynn, Dixon, Cohen, & Murray-Swank, 2008; Mueser, 2003; Pilling et al., 2002). Chronic conditions such as severe mental disorders (Dyck, Hendryx, Short, Voss, & McFarlane, 2002; Hazel et al., 2004; McFarlane, 2002), brain injury (Perlick et al., 2013; Rodgers et al., 2007; Straits-Troster et al., 2013), mild cognitive impairment (Schmitter-Edgecombe & Dyck, 2014) and chronic pain (Smith et al., 2017) have all been studied. A pioneering approach which served as a model for our intervention for SCI was developed by McFarlane in the late 70s for the management of schizophrenia (McFarlane, 2002). The intervention called multiple family group (MFG), provides education, support and problem-solving activities to six to eight persons with schizophrenia and their respective family members. The treatment process is a structured interactive format consisting of two mental health clinicians to assist families and patients to improve coping, social support and illness management skills. McFarlane initially enrolled in-patients with schizophrenia and their family caregivers in a 2-year long intervention. The intervention focused initially on preventing relapse and then gradually shifted focus to rehabilitative and occupational goals with community supports. MFG prevented relapse and re-hospitalization and improved rehabilitation outcomes (cf. McFarlane, 2002), relative to single family groups, and MFG became an evidence based best practice in mental health. In the 1990s, psychiatric hospitalization stays became increasingly shorter and more infrequent as treatment services for persons with severe mental illness shifted to the community. We therefore adapted the MFG intervention to a community mental health care setting (Dyck et al., 2000). We enrolled persons with schizophrenia receiving outpatient services and their family members into a two arm randomized clinical trial comparing a 2-year MFG intervention to Standard Care and demonstrated that relative to standard care, relapse, negative symptoms and hospitalization care and costs were all reduced (Dyck et al., 2000; McDonell, Short, Hazel, Berry, & Dyck, 2006). We also found reductions in family caregiver burden and distress (Hazel et al., 2004).

Adapting multiple family group treatment for brain and spinal cord injury

Approximately 15 years ago Becker, Dyck and colleagues sought to adapt MFG for persons with traumatic brain injury (TBI) and SCI. Below we summarize that treatment development process and the quantitative and qualitative outcome evidence supporting these efforts (Rodgers et al., 2007). We reasoned that although the medical conditions and social and behavioral features of schizophrenia are unique, there are also common themes such as chronicity, the need for illness management skills and community supports and extensive impacts on the family support system. It is also the case that these conditions occur most often in younger age groups, resulting in significant functional disability and restriction of vocational options. These conditions also share the increased risk of social isolation and altered family roles to support the affected individuals. We therefore initiated a field development project to adapted MFG for TBI and SCI. The MFG protocol followed the original model (McFarlane, 1994). The stages included (1) joining with patients and the families through several individual sessions, (2) conducting an educational workshop, and (3) teaching management skills for physical and cognitive challenges as well as improving psychosocial functioning and supports through the use of structured problem-solving group sessions. The group sessions lasted approximately 75–90 min and each consisted of: socialization, go-around, problem identification, and problem solving. We retained the structure and format of the original model but modified the content to accommodate the unique issues of TBI and SCI. For example, during the joining sessions we gathered information on the injury event, its impacts on the patient and the family, how and how successfully they were coping with the adjustments and setbacks. The educational workshop covered neuroanatomy basics, aspects of physical rehabilitation and the support and coping responses to the injury needed by patients and family members. In the problem-solving session, the go-arounds often focused on medical complications, equipment concerns and needs, challenges to travel and caregiver issues. The complete intervention lasted between 12 and 18 months and included initially bi-monthly and then monthly meetings. Two clinicians led each group. The clinicians were experienced physical, speech, and occupational therapists and mental health clinicians (social workers and psychologists). Overall, the results were encouraging. For patients, life satisfaction for patients improved over 18 months (Fig. 1). Patients also reported a decrease in depressive symptoms and anger expression. Among family caregivers, burden was reduced (Fig. 2). Focus groups and qualitative analysis further supported the idea that the MFG experience led to a normalization of the caregiving experience, provided important informational and social support and improved the coping and management skills of both injured persons and their caregivers. Several limitations of this initial effort were that, being a treatment development study, the sample was small, there was no control group and the drop-out rate was approximately 20%. In retrospect, the drop-out rate could be the result of a combination of factors: not enrolling participants early enough after the injury, the length of the intervention, and transportation and related logistic issues.

Comparison of MFG to educational control (EC)

We have recently completed a small randomized clinical trial comparing MFG to an active Education Control (Dyck, Weeks, Smith, & Shaw, 2020). In an effort to improve treatment retention, we shortened the MFG group to 9 months and recruited participants within 3 years of their injury. All participants were provided a copy of the 4th Edition of the book titled: Yes you can: a guide to self-care for persons with spinal cord injury (Hammond, 2000). We block randomized participants (SCI outpatients and their caregivers), in groups of three or four dyads, to either MFG or EC. Participants with SCI and their caregivers were assessed both with psychometrically validated quantitative measures at baseline, at the conclusion of the 9-month intervention and 6 months following the interventions. Focus groups were conducted with all participants at the end of the intervention to determine participants' perceptions of the value of the overall experience, how helpful it was and recommendations for improvement. SCI participants were eligible if they had a paraplegic or quadriplegic injury with complete or incomplete lesion; were discharged from inpatient rehabilitation within 3 years, were living in the community in a non-group setting, at least 16 years old, had a mobility impairment and planned to remain in the geographic area for at least 12 months. SCI caregivers were eligible if they were the primary instrumental and/or emotional support person for a spouse, partner, relative, or friend with SCI, spent at least 2 h of face to face contact per week with the participant, lived with or near the participant with SCI, were at least 18 years old, and planned to remain in the geographical area for at least 12 months. Exclusion criteria included terminal illness with life expectancy of less than 12 months, being in active cancer treatment and cognitive impairment. An overview and global comparison of MFG and the EC interventions is provided in Table 1. The primary difference was that MFG was an interactive experience that provided education, support, and individualized problem solving to participants, while the EC condition was a typical didactic classroom experience with limited opportunity for interaction or individual problem solving. The EC condition covered the topics in the "Yes, you can" book. While content for the MFG condition was loosely based on the book, participants had considerable voice in selecting what problems were identified for problem solving in the sessions. The content comparison between the MFG and EC interventions is shown in Table 2. Treatment integrity in both conditions was supported by videotaping, weekly supervision, and treatment manuals. The results generally supported what we observed in the earlier treatment development study.

Quantitative analyses indicated that following treatment, MFG participants with SCI more frequently disagreed with passive coping statements from the Family Crisis Personal Evaluation Scales (F-COPES; McCubbin, Larsen, & Olson, 1985) compared to EC participants. Thus, MFG group participants more frequently rejected passive coping strategies such as "believing if we wait long enough the problem will go away" that are counter-productive beliefs for rehabilitation. It is important to note that not only did MFG participants with SCI reject passive coping strategies, so too did MFG caregivers. We also found that MFG participants with SCI also reported higher levels of subjective and overall social support on the Abbreviated Duke Social Support Index (ADSSI; Koenig et al., 1993). A number of other quantitative measures such as

TABLE 1 Global comparison of multiple family group (MFG) and education control interventions (EC).

Treatment component	MFG	EC
Therapeutic strategy	Skills training, problem solving, support	Information only
Contents	SCI effects on the body, maximizing function, coping, living and staying healthy with SCI	SCI effects on the body, maximizing function, coping, living and staying healthy with SCI
Target Group	Persons with SCI and caregivers	All persons with SCI and caregivers
Use of group dynamics/ cohesion	*Social support promoted*: Entire group participates in problem-solving for each dyad and gives support and encouragement	*Social support minimized*: Individual health issues not discussed, education is general, group interaction minimized
Therapeutic stance	Educator stance is collaborative	Educator stance is didactic
Room set-up	Round table	Lecture style (all chairs face forward)
Source of material	Drawn from everyday problems brought in by group members	Supplied by educator
Homework	Assigned and reviewed at the start of the following session	Handouts but not homework provided

[a]*The default is two sessions, an optional third session may be used to maintain contact with group members recruited early, or where the dyads are uncertain about continued participation.*
[b]*In addition to basic intake.*

Tables reprinted from Dyck, D. G., Weeks, D. L., Smith, C. L., & Shaw, M. (2020). Multiple family group intervention for spinal cord injury: Quantitative and qualitative comparison with standard education. *The Journal of Spinal Cord Medicine, 44*, 1–11 with publisher permission.

patient activation (Hibbard, Mahoney, Stockard, & Tusler, 2005) and reduced anger expression (Spielberger et al., 1985) approached but did not reach statistical significance, potentially due to a small sample size (Tables 3 and 4).

Qualitative analysis of the focus groups indicated that MFG participants experienced an enhanced sense of belonging and teamwork. They expressed that, the MFG group experience provided them with opportunities to engage with others experiencing similar challenges, which decreased their feelings of isolation. Both participants with SCI and their caregivers requested more and earlier opportunities for this engagement and suggested that the intervention begin while patients with SCI were still inpatients. Participants valued the knowledge and support of the group leaders and spoke at length about their personal ongoing quests for knowledge related to SCI.

Although there were study limitations, such as a small self-selected sample, lack of racial and ethnic diversity and lack of a treatment-as-usual comparison, the results support the earlier treatment development study with a more methodologically rigorous comparison of MFG to an active control intervention.

TABLE 3 Six-step formal problem-solving process utilized in the multiple family group intervention.

Step	Process
1.	Define the problem or goal (MFG members and facilitators)
2.	List all possible solutions (MFG members)
3.	Discuss advantages and disadvantages of each in turn (MFG members and facilitators)
4.	Choose the solution that best fits the situation (MFG members)
5.	Plan how to carry out this solution (facilitators)
6.	Review implementation (facilitators)

Steps are based on brainstorming methods from organizational and business practices.
Tables reprinted from Dyck, D. G., Weeks, D. L., Smith, C. L., & Shaw, M. (2020). Multiple family group intervention for spinal cord injury: Quantitative and qualitative comparison with standard education. *The Journal of Spinal Cord Medicine, 44*, 1–11 with publisher permission.

TABLE 4 Means (standard deviations) per group for significant group main effects in the outcome measures ($P < 0.05$).

		Group		
	Analysis	Multiple family group	Education control	Effect size
Participants with SCI				
F-COPES passive appraisal scale[a]	Pooled imputed	17.7(2.7)	14.9(3.1)	0.9
	Complete case	18.6(2.1)	15.5(2.2)	1.4
ADSSI subjective social support scale[b]	Pooled imputed	19.3(1.5)	15.8(1.7)	2.1
	Complete case	19.4(1.9)	15.4(2.0)	2.0
ADSSI total score	Pooled imputed	27.1(1.8)	24.0(2.1)	1.5
	Complete case	28.1(2.2)	23.2(2.3)	2.1
Caregivers				
F-COPES passive appraisal scale	Pooled imputed	18.3(2.4)	13.9(2.7)	1.6
	Complete case	18.0(2.5)	14.7(2.6)	1.3

Implementation and dissemination opportunities and barriers

While clinicians and researchers consistently request interventions such as MFG to support individuals with SCI (Ebrahimzadeh et al., 2013; Jeyathevan et al., 2019), and the evidence base for MFG SCI and similar group approaches as an important component of outpatient rehabilitation is growing, it is not yet an evidence based best practice. It is, however, important to consider the barriers and opportunities to bridge the chasm between research and practice. In addition to systemic barriers (e.g., cost, effort and reimbursement issues), one of the biggest challenges to recruitment and retention that we have encountered is the high cost of commitment to an intensive long-term intervention with time and travel demands. The time and travel commitments are especially burdensome in the winter for those who live in rural communities impacted by inclement weather. This not only impacts vehicle travel, but often times sidewalks and other paths are not cleared sufficiently for wheelchair use, which makes it even more difficult during an already challenging time. We believe that in this age of telehealth, MFG could be implemented much more readily and likely as effectively through the use of telehealth technology. Choi et al. (2014) recently reported both improved depression and disability outcomes following telehealth delivered (via Skype video call) problem-solving therapy (PST) for depressed, low income homebound older adults. They compared the efficacy of telehealth PST, to in person PST and telephone care calls to homebound older depressed adults. Both telehealth and in person PST were effective treatment, relative to telephone care; however, the effect of telehealth PST on both depression and disability outcomes were sustained longer than those of in-person PST. Although their study was not a group-based intervention for SCI, it is nevertheless a promising example of improving access to care among low income, underserved, home bound adults by providing them with a laptop and wireless card. A systematic review by Gentry, Lapid, Clark, and Rummans (2019) found that videoconference groups were feasible and resulted in similar outcomes to in-person groups, with high participant satisfaction despite some initial technical learning challenges. Additional research was recommended to identify the optimal method of videoconference group delivery to maximize outcomes and benefit.

Application to other areas of neuroscience

MFG is being adapted to other areas of applied neuroscience. We will summarize two areas that we have had direct involvement in: TBI and mild cognitive impairment (MCI).

TBI: TBI survivors and their families experience many of the same challenges that persons with SCI experience. The injury immediately changes the lives of injured persons and their families, especially relationships with spouses. Our initial field development work (Rodgers et al., 2007) adapted MFG for persons with TBI. Given that in the United States TBI became the signature injury of the Gulf wars, there was a pressing need to provide education and support to Veterans with TBI (often with posttraumatic stress disorder (PTSD) as a co-morbid condition). Taking our initial development work with civilian TBI as a starting point, several investigators (Perlick, Troster, and colleagues) sought our collaboration to adapt MFG for military Veterans with TBI (Straits-Troster et al., 2013). Straits-Troster et al. (2013) evaluated the feasibility, acceptability and helpfulness of MFG for veterans of the wars Iraq and Afghanistan who had sustained a TBI, and their family members. Both veterans and family members reported that MFG helped them explore common struggles, reduced their isolation and helped restore and improve relationships, particularly with their spouses. They also reported a better understanding of the connection between TBI and PTSD. The focus group results were similar to those in our work with SCI and TBI and supported the feasibility, acceptability and need for the MFG support program among veterans with TBI. Perlick et al. (2013) reported that treatment was associated with decreased anger expression and increased social support and occupational activity in veterans, while caregivers reported decreased burden and increased empowerment.

Mild Cognitive Impairment (MCI): Schmitter-Edgecombe and Dyck (2014) integrated the MFG intervention with cognitive rehabilitation (CR) for persons recently diagnosed with MCI and their spousal caregivers. The combined intervention was designed to support the adoption of newly learned cognitive strategies including the use of a memory notebook into everyday life. The combined CR-MFG intervention was associated with improved pre-post group differences on measures of everyday functioning and neuropsychological tests of memory. There was also suggestion that care partners noticed the improvements in the everyday functioning of their spouses with MCI. While preliminary, these results suggest that MFG may produce modest functional benefit for persons with MCI. The study also shows that MFG can be successfully combined with other therapeutic strategies. Thus, MFG would potentially have benefit for other neurological conditions such as stroke and multiple sclerosis.

Conclusion

Although significant surgical and related medical advances have been made in improving clinical and functioning outcomes in persons with SCI, for most individuals SCI is a life-changing injury. This is true not only for the person with SCI but also for their caregivers and family members. We are encouraged that functional outcomes for persons with SCI and caregiver support systems can be strengthened by providing education and support through multiple family groups. However, there remain a number of future opportunities and challenges in implementing and refining our systems of care for persons with SCI and their families. The use of telehealth to conduct education and support should be explored to help overcome logistic and access challenges faced by persons with SCI. In our experience, the biggest challenges to successful implementation of innovative practices are often systemic and financial. In this regard, while it can be argued that MFG has been shown to be cost effective in mental health settings by reducing relapse and re-hospitalization, this has yet to be documented in rehabilitation settings. We recommend this as the next primary goal for future research.

Given the substantial social, quality of life and medical costs of SCI to affected individuals and their families, it is critical to explore methods to reduce these burdens. These costs are unlikely to diminish in the future through existing technology. The multiple family group education process has been shown to reduce the impact of some of these burdens humanely, safely, and with reasonable efficiency. It deserves front-of-mind consideration in the management of spinal cord injury care.

Summary points

a. Spinal cord injury is an unexpected event that immediately and permanently changes the lives of those who experience it and the lives of their loved ones.
b. The majority of persons with spinal cord injury are discharged to home under the care of family members after increasingly abbreviated hospitalization.
c. Family caregivers are often as stressed and overwhelmed as persons with spinal cord injury by the adjustments needed. There is a pressing need for individualized education and support for caregivers.
d. Evidence from research on other chronic medical and psychiatric conditions indicates that individualized education, problem solving, and support provided in a group format improves clinical outcomes.
e. Multiple family group is a group intervention that provides clinical care, support and individualized education to persons with spinal cord injury and their caregivers.
f. In persons with SCI, multiple family group was found to decrease depressive symptoms, anger expression, and passive coping and to increase life satisfaction and levels of subjective and overall social support.
g. Multiple family group participants experience an enhanced sense of belonging and teamwork, reduced isolation, increased knowledge and support.
h. Multiple family group intervention has relevant applications to other areas of Neuroscience such as Traumatic Brain Injury and Mild Cognitive Impairment
i. Implementation and dissemination opportunities and challenges, including telehealth and system and financial barriers should be considered for future dissemination of the multiple family group intervention.

VR	vocational rehabilitation

Introduction

Community integration includes having access to appropriate housing, being able to mobilize in the community, being able to participate in work, leisure or educational activities of choice, and engaging in satisfying social relationships (Barclay, Lalor, Migliorini, & Robins, 2020; Chang, Coster, & Helfrich, 2013). It is synonymous with the term *participation* in the International Classification of Functioning Disability and Health (ICF) (World Health Organization, 2002), which refers to involvement in life situations, and includes active engagement at the community level and social connectedness with other people (Hammel et al., 2008). Participating in meaningful roles and interests in the community, such as leisure and employment, can enable a person to reframe their views on acquired disability (Kratz, Chadd, Jensen, Kehn, & Kroll, 2015), but poor community integration and lack of social participation is one of the biggest challenges for someone following SCI (Craig, Nicholson Perry, Guest, Tran, & Middleton, 2015). Services and models for SCI rehabilitation need to prioritize community integration in order to maximize outcomes and quality of life.

Prioritizing community integration

Following SCI a person will usually spend several months undergoing inpatient rehabilitation in a specialized spinal unit (Dwyer & Mulligan, 2015). Following this, the injured person will be discharged to live in either their own home, or some other form of temporary or alternate accommodation. This period of transition from hospital to home is a very challenging time for people, as they are removed from the safety of the hospital environment with the associated supports, both physical and social, and plunged into environments that may be inaccessible and even hostile toward people with disabilities (Nunnerley, Hay-Smith, & Dean, 2013). This process is made more challenging for people in developing countries, where community infrastructure such as roads, and transport is even less accessible for people with disabilities (Liu et al., 2020). The funding environment, policies and infrastructure in the jurisdiction in which the injured person lives, impacts the availability of the resources they have access to, and may facilitate or hinder this transition process. People with SCI have described feeling unprepared for the difficulties and barriers they are going to face in the real world (Nunnerley et al., 2013). Therefore, in the context of shrinking health budgets, maximizing the efficacy of inpatient rehabilitation to prepare people to reintegrate into their community must be one of the primary goals of rehabilitation (Kratz et al., 2015).
